

**Development of highly efficient
electrocatalysts for fresh and seawater
electrolysis under high current density**

ABSTRACT

Hydrogen production via electrochemical water splitting is a clean and secure technology. Water electrolysis consists of two main reactions, i.e., Hydrogen Evolution Reaction (HER) and Oxygen Evolution Reaction (OER). However, the sluggish OER kinetics and high-cost of commercial noble metal based catalysts such as Pt and RuO₂ based ones limit the practical application of this technology. Especially, to meet the practical industrial-scale requirements, the electrocatalysts should be operated at a high current density to achieve a high hydrogen production rate under long-term operation. Besides, using seawater directly to replace freshwater for the hydrogen production is attracting more and more attention for sustainable energy development because seawater is abundant. However, utilizing seawater based electrolyte remains great challenge due to the existence of competitive reactions between chlorine evolution reaction (CER) and OER at the anode in the presence of Cl⁻ in the seawater, which always results in catalyst degradation and serious electrode erosion. In this dissertation study, the objective is to develop highly efficient electrode for water splitting with minimized operation cost, especially at a high current density even in a natural seawater based solution.

Firstly, CuVO_x@NiO nanosheet is successfully synthesized using a facile one-step hydrothermal process combined with a calcination method. The obtained CuVO_x@NiO composite electrode exhibits remarkable HER activity in alkaline freshwater solution with an overpotential as low as 74 mV at 10 mA cm⁻², which also shows excellent stability and a fast kinetic reaction with a Tafel slope of 60.8 mVdec⁻¹. Moreover, it can maintain the potentials at difference constant current densities up to 300 mA cm⁻². Such a higher electrocatalytic performance could be attributed to the generation of real active (VO_x-Cu₂O) species during HER with increased O vacancies. Besides, lamellar NiO shell could also provides a large number of active sites and super-hydrophilic surface, which effectively facilitates the H₂O adsorption and decomposition to H_{ads} intermediates. It is found that the intrinsic reaction activity for the conversion of H_{ads} to H₂ could be improved by the VO_x-Cu₂O core with rich O vacancy defects. This pioneer work provides a novel catalyst structure and superb properties for the HER in the alkaline electrolyzer.

Secondly, *in-situ* growing of FeNiS_x/NiFe(OH)_x on nickel foam (NF) is successfully realized using a facile corrosion engineering followed by a fast and mild sulfurization process. The obtained electrode requires only a low overpotential of 270 mV at a high current density of 100 mA cm⁻² in alkaline simulated seawater (1 M KOH + 0.5 M NaCl) and maintains mechanical stability at an industrial-level current density of 1 A cm⁻² without catalyst corrosion. Density functional theory (DFT) calculations reveals that the FeNiS_x/NiFe(OH)_x has high oxygen evolution reaction (OER) against chlorine evolution reaction (CIER) since S substitution on O site can effectively decrease the free energy gap between *OH to *O, making OER more efficient. For overall seawater electrolysis using it as the bifunctional electrocatalyst, the electrolyzer only requires a low cell voltage of 1.60 V at 10 mA cm⁻² and can sustain stable at the industrial-level current density of 1 A/cm² with a cell voltage of 2.81 V for 100 h, achieving a high hydrogen productivity without the catalyst deterioration.

Lastly, a MnCo₂O₄ nanowire coated with NiFe-Layered Double Hydroxide (NiFe-LDH) layer (MnCo₂O₄@NiFe-LDH) composite electrocatalyst prepared by a simple two-step hydrothermal method is applied for the seawater electrolysis, which exhibits low overpotentials of 219 and 245 mV for OER at a high current density of 100 mA cm⁻² in alkaline simulated and natural seawaters, respectively. It is found that the NiFe-LDH layer on the MnCo₂O₄ nanowire can serve as Cl⁻ protective layer to hinder the CIER and anode erosion and simultaneously improve the active surface area and intrinsic properties of MnCo₂O₄ nanowires, allowing for faster kinetics. While, the high valence states of Mn³⁺, Co³⁺, Ni³⁺ and Fe³⁺ play a crucial role for OER. In addition, when it is used as the bifunctional electrocatalyst for the overall natural seawater splitting, the MnCo₂O₄ @NiFe-LDH (-)||MnCo₂O₄ @NiFe-LDH(+) pair in a two-electrode cell only requires a low voltage of 1.56 V@10 mA cm⁻² and simultaneously maintains excellent stability at a high current density of 100 mA cm⁻² for over 100 h. Such an electrocatalyst could be a promising candidate for practical seawater splitting.

ACKNOWLEDGEMENTS

I would like to express my deepest appreciation to Professor Dr. Guoqing Guan for providing me with the opportunity to study for PhD degree at Hirosaki University, as well as knowledges, suggestions, guidances, feedbacks, encouragements, supports and patience for my research and daily life during my PhD program. Thank you for being so kind and accommodating for solving so many problems. I feel so lucky to be one of your students.

I am extremely grateful to Professor Abuliti Abudula for all guidances and advices on my research.

I would like to acknowledge to Dr. Li Xiumin and Dr. Yufei Ma for their advices and proofreading for my manuscript.

I am also thankful to all professors and staffs at Institute of Regional Innovation (IRI) and Graduated School of Science and Technology, Hirosaki University, for all kind supports.

I also could not have undertaken this journey without Dr. Nichaboon Chaihad, who introduced me to this laboratory and has always been the best sister.

I would like to extend my sincere thanks to all members in our group, PhD alumni and classmates for all their suggestions and discussions, as well as their assistances in repairing the machine, waiting for me to return home and providing emotional supports. Thank you for making this a memorable experience.

Thank you to all of my friends and seniors from all countries, especially those from Hirosaki University, Mahidol University, Chulalongkorn University, Samsen II and Kao Consumer Products (Southeast Asia), for their practical and emotional supports.

Many thanks to my idol for inspiring and motivating me during a difficult time.

I would like to thank Japanese government for the financial support during the Covid-19 situation in Japan.

Lastly, I would be remiss in not mentioning to my family, especially my parents for all motivation, supportive, and belief in me.

Finally, this endeavor would not have been possible without the generous support from Ministry of Education, Culture, Sports, Science, and Technology (MEXT) of Japan for fully supports throughout my Ph.D. study at Graduate School of Science and Technology, Hirosaki University.

Thank you all very much.

Nutthaphak Kitiphatpiboon

CHAPTER 1 Introduction

A most promising energy carrier for a decarbonized global energy system is hydrogen. As reported by International Renewable Energy Agency, the hydrogen market will reach \$ 155 billion by 2022, and the market share of water electrolysis for hydrogen production is expected to reach 22% by 2050 [1]. Especially, the hydrogen production via water electrolysis is a promising option in the environmental friendly way without green house gas emission. The reaction takes place in a unit called an electrolyzer. There are many types of electrolyzers categorized by charge carrier, operation temperature and electrolytes including alkaline electrolysis, polymer electrolyte membrane electrolysis (PEMWE) and solid oxide electrolysis (SOE) [2]. In this study, the electrochemical decomposition of water at a low temperature (below 100°C) with an aqueous electrolyte is chosen due to its low operating cost and safety. Theoretically, water electrolysis involves two half-cell reactions, i.e., hydrogen evolution reaction (HER) at the cathode and oxygen evolution reaction (OER) at the anode, in which HER and OER have thermodynamic equilibrium potentials of 0 V and 1.23 V vs. RHE, respectively (Figure 1.1). Because water splitting is not a spontaneous reaction, the input voltage should be high enough to overcome the overpotentials of the HER/OER reactions in order to split water molecule into hydrogen and oxygen [3].

Precious metals (e.g., Ir, Ru) and their oxide compounds (e.g., IrO₂, and RuO₂) are currently used as the benchmark electrocatalysts on the anode side in water splitting. While, Pt based ones are widely used on the cathode side. However, their scarcity, high cost and poor durability from metal dissolution after long-term operation limit their large-scale applications [4, 5]. Therefore, non-precious metal-based catalysts with superior performance and low price are required.

The major obstacle of electrolyzer efficiency is the overvoltage or overpotential

for OER at the anode because of the sluggish kinetics caused by the 4-electron transfer step. Thus, it is more important to develop OER electrocatalysts. To date, only a few electrodes can meet the criteria for an industrial application, by which OER can work stably at an extremely high current density ($\geq 500 \text{ mA cm}^{-2}$) with a low overpotential ($\leq 300 \text{ mV}$) for a long-period [6]. Many electrocatalytic systems based on acidic, alkaline, and neutral freshwater electrolytes have been explored. Recently, utilizing the earth abundant seawater (96.5% water resources on earth) to replace freshwater attracts more and more interests for promoting the sustainable energy development goals (SDGs). However, it is full of challenges relating to high energy cost and serious chlorine erosion in seawater environment. More than 3.5% of salts consisting of Na^+ , Cl^- , Ca^{2+} , Mg^{2+} , and so on in the seawater, which could affect both HER and OER. In the alkaline condition, the formation of insoluble compounds can poison the electrocatalysts at both the cathode and anode, resulting in catalyst deterioration and deactivation, lowering electrocatalytic activity and stability [7].

The barrier for utilizing the natural seawater is that the aggressive Cl^- anions can lead to chlorine evolution reaction (CER) with the formation of hypochlorite at an overpotential about 480 mV in an alkaline electrolyte. As such, the competitive reaction between OER and CER always occur since CER is more kinetically favorable via a two-electron transfer pathway [8, 9]. The competitive reaction between OER and CER on the anode site can be suppressed by limiting the OER overpotential lower than 480 mV under alkaline condition ($\text{pH} > 7.5$) [10]. To date, long-term stability at an industrial current density of $\sim 1 \text{ A cm}^{-2}$ is still not applied in seawater splitting [9]. While, it is expected to have ideal bifunctional electrocatalysts with low-cost, highly activity, long-term durability for HER/OER and cost-effective preparation method for practical application [29].

Figure 1.1 Schematic illustration of water electrolyzer with two half-reactions under acidic and alkaline conditions.

1.1 REACTION MECHANISM OF WATER ELECTROCATALYSIS

1.1.1 Theoretical of hydrogen evolution reaction (HER)

HER is kinetically favourable in acidic solution because of high proton concentration. In acidic solution, HER performance is related with hydrogen adsorption (H_{ad}), which follows Volmer/Heyrovsky or Volmer/Tafel steps as indicated below [11]

In the alkaline solution, The Volmer step refers to the reduction of water molecule on the catalyst surface to form adsorbed hydrogen atoms and hydroxide anion. Consequently, two possible mechanisms could occur : (i) Heyrovsky step, in which the adsorbed hydrogen (H_{ad}) atom from the volmer step is reacted with another water molecule, producing a H_2 molecule and a OH^{-} (Volmer-Heyrovsky) and (ii) Tafel step, in which two adsorbed hydrogen atoms from volmer step can be combined to generate

a H₂ molecule (Volmer-Tafel) as shown in the following equations [12, 13]:

The whole reaction rate is mostly based on the the hydrogen adsorption free energy (ΔG_H). The adsorption (Volmer) step will hinder the whole reaction rate if the H₂ molecule weakly adsorbs on the surface of catalyst. On the other hand, the desorption via Heyrovsky or Tafel step will reduce the reaction rate if the hydrogen binding is so strong on the surface of catalyst. Therefore, the highly active HER catalyst should have $\Delta G_H \approx 0$ (but inadequate) with optimal binding energy between reaction intermediate and catalyst surface [14].

1.1.2 Theoretical of oxygen evolution reaction (OER)

A 4-proton-coupling electron transfer step is involved in OER, which is always the bottleneck for water splitting. There are two possibiles mechansims for OER, including (i) adsorbate evolution mechanism (AEM) and (ii) lattice-oxygen-mediated mechanism (LOM) [15].

The conventional AEM has been proved by the Sabatier principle, that is, the oxygen adsorption energy on catalyst surface [16]. AEM is being considered to be involved in 4-electron transfer pathway on the active metal sites. For this mechanism, the H₂O molecule is first binded on the metal active sites with the generating of an adsorbed OH^* on the metal sites (*). Subsequently, *OH couples with proton with an electron removal process to generate *O intermediates. Following the formation of O-O bond, *O can combine with another H₂O molecule to generate *OOH , which will be finally,

oxidized, leading to the O₂ release and the regeneration of the initial Metal active sites as illustrated in the following equations:

Where, the * denotes as a catalytic active sites on the catalyst surface while OOH^* , O^* and OH^* represent three adsorption intermediates. Theoretical OER potential is 1.23 V at the standard condition with the overall reaction Gibbs free energy (ΔG) of 4.92 eV. In the equilibrium state, however, from the above equations, each step should be related to a specific binding energy corresponding to the intermediates. The rate-determining step (RDS) is the step with the largest free energy gap ($\Delta G = \max [\Delta G_1, \Delta G_2, \Delta G_3, \Delta G_4]$), and the theoretical overpotential of the reaction can be calculated by $\eta_{OER} = \frac{\Delta G_{max}}{e} - 1.23V$ equation [17, 18].

Lattice-oxygen-mediated mechanism (LOM) is attributed to the dynamic catalyst surface, not only active sites at the metal centers but also lattice oxygen. The first two steps of LOM are similar to AEM by forming O^* . Then, O^* will interact with the lattice oxygen to generate a O₂ molecule, forming a lattice oxygen vacancy. Finally, the migration of OH^- from the solution can refill the oxygen vacancy. According to this mechanism, oxygen species in the lattice functions as the intermediate and thereby, there is no OOH^* to be formed in this pathway. Thus, the lattice oxygen evolved in OER plays a crucial role for boosting the OER activity. Theoretically, the $\Delta G^{OER} = 1.23 \text{ eV}$, however, there is a difference between theoretical and experimental values caused by inappropriate electrocatalyst O-bonding forces, which makes OER more sluggish. The RDS for OER can be investigated from the Tafel slope. The first reaction

is the rate-controlling step if Tafel slope is around 120 mV dec⁻¹ (Eq. 7). At the same time, if the Tafel slope is approximately 40 mV dec⁻¹, the second reaction performs as a rate-determining step (Eq. 8) [19].

In acidic solution

Overall oxidation reaction under the standard condition (pressure = 1 bar and T = 298.15 K) in acidic solution can be expressed as below ;

where ΔG refers to Gibbs free energy. The reaction mechanism consists of 4 steps ;

where the * denotes catalytic active sites on the catalyst surface, and $*OOH$, $*O$ and $*OH$ represent adsorption intermediates.

In alkaline solution

Overall oxidation reaction under standard condition (pressure = 1 bar and T = 298.15 K) in alkaline solution can be given by [20]

In this case, the OER mechanism under alkaline condition can be described by 4 steps using the equations below [20]:

According, OER is more kinetically sluggish in a water electrolysis cell, and OER is always a crucial reaction in controlling the overall efficiency of overall water splitting [21].

1.1.3 Overall water splitting

To complete the overall water splitting reaction, electrocatalysts must perform well on both cathode and anode sides. The overall reaction can be described in the following equations[22]:

Overall reaction ;

In acidic solution ;

In alkaline solution ;

The thermodynamic equilibrium potential for the overall water splitting is 1.23 V under standard temperature and pressure (STP) conditions (T = 25°C and P = 1 atm) with 0 and 1.23 V vs. RHE for cathodic and anodic, respectively. Nevertheless, the practical cell voltage (V_{oc}) of water electrolysis is far from this theoretical potential. Thus, the overpotentials for cathode (η_c) and anode (η_a), and the extra potential to compensate for internal resistance loss (η_{Ω}) need to be considered as indicated in Eq. 26:

$$V_{oc} = 1.23 \text{ V} + |\eta_c| + \eta_a + \eta_\Omega \quad (\text{Eq.26})$$

1.1.4 Chlorine Evolution reaction (CIER)

In the seawater splitting, two-electron transfer reaction of CIER is more kinetically favorable than OER. Thus, directly using seawater remains challenge. Pourbaix diagram is commonly used to explain the thermodynamic behavior of chlorine species in various pH values [23], in which the thermodynamic gap in each pH value should be considered in order to avoid the occurring of CIER.

1.1.4.1 Seawater electrolysis at low pH value

The competitive reaction between OER and CIER at the anode side must be taken into account especially in the acidic solution ($\text{pH} < 3$). In this case, the formation of chlorine is illustrated in Eq. (27). As shown in Figure 1.2, the overpotential gap between OER and CIER is less than 330 mV, and it is obvious that the chlorine is more easily generated in the electrolyte with a low pH.

1.1.4.2 Seawater electrolysis at neutral pH value

As shown in Figure 1.2, increasing the pH of the solution ($3 < \text{pH} < 7.5$) causes the formation of hypochlorous acid (Eq. (28)). However, because of the sluggish kinetics of water dissociation in neutral/near-neutral solutions, improving catalytic performance and OER selectivity at this pH range is more difficult.

1.1.4.3 Seawater electrolysis at high pH value

In alkaline solution, the thermodynamic gap between potentials required for OER and formation of ClO^- is about 480 mV for CIER, with a larger gap than the case with a lower pH value (Figure 1.2). In summary, the formation of HClO/ClO^- is commonly simplified as described below [24]:

- (i) Chloride migration to the anode, where it is oxidized to gaseous chlorine

(ii) Chlorine hydrolysis results in the formation of hypochlorous acid (pH <3)

(iii) pH-dependent equilibrium between hypochlorous and hypochlorite ion (3 <pH<7.5)

(iv) Competitive reaction between OER and ClER at the anode side in alkaline solution (7.5 <pH<14) ; [25]

According to Eqs. (30) and (31), the potential difference between OER and ClER in the alkaline solution is ca. 480 mV at the pH range of 7.5-14. Hence, if OER overpotential is lower than 480 mV, ClER could be avoided. The ClER generation mechanisms in various pH values can be found in Table 1.1.

Figure 1.2 Computed Pourbaix diagram for artificial seawater model [9].

Table 1.1 Reaction mechanism in a different conditions[26].

Electrolyte	pH values	Half-cell reaction	E ⁰ (V)
Acid solution	pH < 3	$2Cl^- \rightarrow Cl_2 + 2e^-$	+1.36
Neutral solution	3 < pH < 7.5	$Cl^- + H_2O \rightarrow HClO + H^+ + 2e^-$	+1.61
Alkaline solution	pH ~14	$Cl^- + 2OH^- \rightarrow ClO^- + H_2O + 2e^-$	+0.89

The presence of chloride ions in natural seawater have an effect on both anode and cathode. Chloride ions on the anode may hinder HER by adsorption on the catalyst active sites, promoting catalyst degradation. On the other hand, high OER selectivity need to be considered for designing the potential electrode for OER at the anode. As a result, developing highly efficient bifunctional electrocatalysts for seawater splitting remains challenging.

1.2 CATHODE MATERIAL DESIGN FOR HER

1.2.1 Transition metal oxides (TMOs) and Hydroxides (TMOHs)

Transition metal oxides have been applied for HER owing to their abundant crystal structures and excellent activity. For example, Gong *et al.* [27] mentioned that Ni@NiO/Cr₂O₃ had excellent HER activity and stability comparable to Pt based electrocatalysts since the chemically stable Cr₂O₃ can prevent oxidation and aggregation of Ni core, and maintain abundant NiO/Ni active sites for HER in alkaline solution. Lu *et al.* [28] reported that Mn-doped nickle oxide/Ni (Mn-NiO/Ni) heterostructure also had Pt-like performance with a low onset potential even in natural seawater (pH ~8.2). Wu *et al.* [29] demonstrated that incorporating Ru into CoO_x/NF can effectively improve catalytic activity at large current densities. This electrode required only 252 mV overpotential at a large current density of 1 A cm⁻², which is better than that of Pt/C (444 mV). Moreover, the catalytic activity remains constant for

100 h, indicating that it is a highly durable electrode [29]. Jiang *et al.* [30] prepared NiFe-LDH/FeOOH on nickel foam substrate via an electrodeposition process, which showed a low overpotential of 181.9 mV @10 mA cm⁻² for HER in 1 M KOH + 0.5 M NaCl solution. The results proved that the formation of NiOOH species during reaction and strong interaction between FeOOH and NiFe-LDH are able to improve catalytic activity.

1.2.2 Transition metal alloys (TMAs)

Precious metals and their alloys like Pt and Pd alloys have been studied for HER in alkaline solution due to excellent catalytic activity and electrical conductivity. However, high cost limits their large-scale application. As such, cost reduction through the modification of noble metals with transition metal alloys is widely considered. According to Brewer-Engel theory, d-orbital atoms in a half- or full-space state should be more beneficial for the adsorption of H atom, and electrons are able to activate H₂O molecule via the d orbitals so that the O-H bond is broken. Thus, alloying of Pt with various transition metals could vary the performance of HER [31, 32]. As indicated above, the HER activity in seawater splitting is extremely challenging since its intrinsic corrosive nature [28]. Thus, many strategies have been studied for improving the electrocatalytic activity and stability in seawater solution. For example, It was discovered that altering the noble metal catalyst electronic structure by doping foreign atoms like Ni, Fe, Mo, Co, Cr and so on could mitigate the influence of Cl₂ on Pt performance effectively with the enhanced stability. While, it can also facilitate the charge transfer process and effectively enhance the activity, particularly in seawater solution [33]. Zheng *et al.* [34] reported that Ti supported PtPd alloy electrode exhibited an onset potential of 52 mV with an excellent efficiency for HER because the alloying of Ni with Pt has a potential to tune electronic structure and change the transfer of

charge while more active sites could be exposed on the nanostructure, thereby improving HER performance. While, the Ti/PtMo electrode showed a low overpotential of 254.6 mV to achieve 10 mA cm^{-2} in seawater solution. Moreover, it is found that the competitive dissolution reaction between Mo and Pt in seawater that produces Cl_2 is advantageous for increasing the durability of PtM alloy electrodes. As such, the optimized PtMo alloy catalyst maintained the initial current density about 91.13% over 172 h in seawater. Besides, PtNi₅ electrode was used to catalyze the HER reaction in seawater solution, which displayed the most excellent performance with a minimum starting potential of 380 mV and maintained stable for more than 12 h [35]. Ros *et al.* [36] proposed an electrocatalyst of Ni-Mo-Fe trimetallic coated on graphitic carbon felt for HER in real seawater, by which a two-electrode cell required 1.58 and 2.16 V at 10 and 100 mA cm^{-2} , respectively.

1.2.3 Transition metal sulfides (TMS)

Theoretically, in the layered MS_2 with a sandwich structure, one metal layer bonds to two sulfur layers. Because van der Waals forces are relatively weak, each MS_2 unit cell is vertically stacks on top of others, allowing MS_2 to be exfoliated down to single layers. They are classified into several phase types including 1T, 2H, and 3R phases (here, the digit represents the number of layer; T, H and R respectively refer to tetragonal, hexagonal and trigonal lattices) based on MS_2 bonding configurations. The electronic structure of MS_2 varies with the configuration [37]. Transition metal sulphides with high electrical conductivity can be utilized for HER. In this case, to achieve higher electrocatalytic activity, the synthesis method and various modified strategies have been proposed. For example, doping a transition metal into sulphide-based materials can effectively increase active sites and optimize the 3d electronic configuration [38]. He *et al.* [39] used a cationic doping strategy to tune

electrocatalyst's electronic structure as well as the free energy of the adsorbed intermediate. They synthesized Zn-doped Ni_3S_2 , which displayed a low overpotential of 78 mV @10 mA cm^{-2} and maintained stably for at least 18 h in alkaline solution, implying its high HER activity and durability. To explore the reaction mechanism during HER, DFT calculations are always applied to investigate the adsorption/desorption ability of intermediates on the active sites during the reaction. For example, Zhang *et al.* [40] studied the electrocatalytic activity of Ni_3S_2 toward HER, and DFT calculation results demonstrated that S-rich surfaces and several stoichiometric of Ni_3S_2 surfaces are thermodynamically stable, thereby increasing HER activity. Pan *et al.* [41] synthesized pentagonal 2D transition metal sulphide monolayer such as FeS, MnS and VS. Among them, FeS and VS monolayers exhibited superior activity for HER in acidic electrolyte, and it is found that they had lower Gibbs free energies when compared to other materials. Xie *et al.* [42] synthesized MoS_2 using a defect engineering strategy and found that the molar concentration of Mo to S played a significant role in the determining of the number of active sites. Thus, the defect-abundant MoS_2 demonstrated remarkable HER activity with an onset potential as low as 120 mV. However, it is found that there was limited the active sites in the bulk MoS_2 . To solve this issue, they tried to expose more active sites of MoS_2 by incorporating oxygen into MoS_2 nanosheets, by which a large number of defects were generated. Notably, the generation of defects could provide more active sites whereas the O doping could increase electrical conductivity [43]. Duraisamy *et al.* [44] synthesized $\text{MoS}_2/\text{MoO}_3$ by a one-step hydrothermal synthesis. It is found that the 1T/2H- MoS_2 and 1T- $\text{MoS}_2/\text{MoO}_3$ have rich defects, which effectively enhanced the HER activity in acidic solution. Moreover, rich S vacancies in substoichiometric MoS_{2-x} and rich O-vacancies in substoichiometric MoO_{3-x} edge sites of nanosheets serve as active sites for HER.

1.2.4 Transition metal phosphides (TMPs)

TMPs have been applied for hydrogen production due to their excellent conductivity, high corrosion resistance and high catalytic activity. Herein, the electronegative P atoms can accelerate H₂ dissociation and the optimal atomic ration between metal and P can improve conductivity and P alloying can enhance the corrosion resistance and chemical stability for HER [45, 46]. Moreover, bimetallic phosphides (such as NiCoP, CoFeP, and CoMoP) are more active than monometallic phosphides. For example, Pan *et al.* [47] mentioned that multi-phase heterostructure CoNiP/Co_xP/NF catalysts exhibited an overpotential as low as 36 mV@10 mA cm⁻², outperforming commercial Pt/C. According to DFT calculations, the strong electronical interaction at CoNiP/CoP heterointerface could be attained by transferring of electron from CoNiP to the heterointerface, which can promote water dissociation at the heterointerface and enhance the desorption of hydrogen from CoNiP, resulting in high activity and stability under alkaline seawater solutions. Wu *et al.* [48] proposed a Ni₂P-Fe₂P/NF electrode for alkaline seawater splitting, which needed only low overpotentials of 252 and 389 mV at 0.1 and 1A/cm², respectively. This 2D nanosheet structure contained abundant of active sites, which played a crutial function for improving the activity. Furthermore, the Ni and Fe species could help to improve stability and corrosion resistance, which is advantageous for seawater solutions.

Many strategies such as interface engineering, doping, and defect engineering are usually applied to modify the electronical structures of TMPs in order to improve catalytic activity. Especially, interface engineering is immensely used to optimize activity by tuning the electronical structure of catalyst, increasing active sites, and promoting mass transfer [49]. Recently, it is reported that TMPs had superior activity and stability in seawater splitting. For example, Chang *et al.* [50] successfully

synthesized Fe, P-NiSe₂ electrocatalyst, which required only 120 and 180 mV at 0.1 and 0.5 A/cm², respectively, in 0.5 M KOH + seawater solution with 90% IR correction. Herein, the P-NiSe₂ active sites should be formed by Fe cation doping whereas the P anions resulted in the formation of a passivation layer containing P-O bonds, improving electronical conductivity and preventing selenide dissolution. Yu *et al.* [51] prepared a sandwich-like NiCoN|Ni_xP|NiCoN microsheet array based electrode, which also displayed superior HER performance with a low overpotential of 165 mV @10 mA cm⁻² in natural seawater electrolyte, and can be operated for 24 hour under seawater electrolysis (@10 mA cm⁻²). Herein, the superior performance and stability could be attributed to (i) high chlorine-corrosion resistance from Ni_xP skeleton and (ii) anti-corrosive NiCoN nanoparticles [51].

1.2.5 Transition metal carbides and nitrides (MXenes)

The new class materials of 2D transition metal carbides, nitrides and carbonitrides are named as MXenes, which are especially suitable for engineering in order to achieve multi-functional catalytic interfaces with high active surface area [52]. MXenes is generally expressed as M_{n+1}X_nT_x (n = 1-4), where M represents early transition metal atoms (i.e. Ti, Zr, Nb, and V), X is C or N, T_x is the surface termination group (i.e. – F, –OH, –O, –Cl or –Se) and M layers cover the X layers in [MX]_nM arrangement [53]. MXene interlayer spacing is typically in the 1 nm range and it can be determined by the value of n in MXenes (M_{n+1}X_nT_x) [54]. The surface termination groups can induce hydrophilic surface and the layered structure could provide a large surface area. Thus, it has been suggested as a potential candidate for water electrolysis [55]. Moreover, the molecular sheets produced from transition metals carbides and nitrides can offer a high carrier mobility and intrinsic layered structure, indicating inherently superior conductivity and excellent volumetric capacitance. As such, the electrocatalytic

performance of MXene should depend on transition metal type, morphology, surface termination groups, adsorption and desorption ΔG_H values, and elemental doping state. Recently, it is reported that MXenes have great potentials as the electrocatalysts for water electrolysis because of its some special advantages including large surface area, excellent metallic conductivity (up to $10,000 \text{ S cm}^{-1}$), good hydrophilicity and adjustable structure [56]. For example, Tian *et al.* [57] synthesized FeCo-LDHs on a single-layered MXene ($\text{Ti}_3\text{C}_2\text{T}_x$), which showed an overpotential as low as 268 mV @ 10 mA cm^{-2} for OER in alkaline solution. Herein, the MXene effectively stabilized the LDH structure against aggregation with a synergistic effect with FeCo-LDH and especially, the high conductivity of MXene sheet can accelerate the redox process during the OER reaction, thereby leading to an excellent electrocatalytic activity. Haiyuan *et al.* [58] synthesized a hierarchical porous NiCuS/ $\text{Ti}_3\text{C}_2\text{T}_x$ electrocatalyst using a metal-organic framework (MOF) precursor. It is found that the interfacial interaction between NiCuS and Ti-MXene sheets effectively increased active sites, enhanced charge transfer rate and facilitated the electrolyte diffusion in the open structure. As a result, outstanding OER activity with an overpotential of 365 mV @ 10 mA cm^{-2} was achieved. Sun *et al.* [1] used a NiCo@C/MXene on CF anode coupling with a hydrazine degradation to generate H_2 . This electrode exhibited a best HER activity with low overpotentials of 49 and 235 mV at 10 and 500 mA cm^{-2} , respectively. The higher performance could be attributed to (i) the superior conductivity of $\text{Ti}_3\text{C}_2\text{T}_x$ MXene, (ii) the abundance -O and -OH groups on MXene surface, which can effectively facilitate the water as well as hydrazine molecules attractions onto the interface via hydrogen bonding, and (iii) hydrophilic properties, which can accelerate the overall kinetics. Moreover, it can work stably and produce H_2 gas at a rate of $9.2 \text{ mol h}^{-1} \text{ g}_{\text{cat}}^{-1}$ for 140 h at 0.5 A cm^{-2} with an excellent Faradaic efficiency, implying high mechanical

robustness in corrosive seawater splitting with 30-52% cost reduction at the high current density. To improve HER performance in natural seawater, Wu *et al.* [59] designed a multifunctional $\text{Co}_x\text{Mo}_{2-x}\text{C}/\text{MXene}/\text{NC}$ electrode by using a cooperative catalytic interface strategy, which only required the overpotentials of 81, 126 and 75 mV at 10 mA cm^{-2} for HER in 0.5 M H_2SO_4 (pH 0.3), 0.1 M phosphate buffer (PBS, pH 7.01) and 1.0M KOH (pH 13.8), respectively. Herein, the extremely conductive MXene can accelerate the transportation of charges across the triple-phases interface (catalyst-electrolyte-gas) and enhance H^+ /water adsorption on the catalyst with a lower kinetic barrier for water dissociation. While, the $\text{Co}_x\text{Mo}_{2-x}\text{C}$ provided highly exposed active surface area with substantial exposure active sites for promoting the HER. Therefore, the collaborative interface between $\text{Co}_x\text{Mo}_{2-x}\text{C}$, hybridized carbon and MXene can effectively enhance the kinetics of initial Volmer step balance adsorption/desorption (H^* and H_2) and maintain the stability in a wide pH range and natural seawater with 98% Faradaic efficiency.

1.3 ANODE MATERIAL DESIGN FOR OER

1.3.1 Transition metal oxides/hydroxides/ oxyhydroxides

Transition metal oxides or (oxy) hydroxides, especially first-row of transition metals (e.g., Mn, Fe, Co and Ni) base ones have been intensively studied for a OER since oxygen in the metal oxides and (oxy)hydroxides lattices could associate with the surface reaction and play a crucial role for modulating the catalytic performance [60]. For example, in the alkaline condition, it was mentioned that an amorphous $\text{NiFe}(\text{OH})_x/\text{CP}$ electrode exhibited a low overpotential of 303 mV @ 0.1 A cm^{-2} with a small Tafel slope of 33.8 mV dec^{-1} [61]. Herein, the superior activity toward OER could be attributed from the generation of oxygen vacancies, synergistic function between Ni and Fe species with an optimal Ni/Fe ratio. Recently, He *et al.* [62] reported that Mo

doing in NiFe (oxy)hydroxide can effectively improve oxygen activity via a lattice-oxygen-mediated (LOM) pathway. By using the metal-oxygen bond strength as a representative of oxygen activity for DFT calculation, it is proved that doping of Mo can weaken the metal-oxygen bonds and activated the lattice oxygen due to the upshift of O 2p, referring to deeper penetration of Fermi level into the O 2p band, which enhances the electron movement from oxygen sites, allowing lattice oxygen to be released from lattice more easily, thereby promoting the formation of oxygen vacancies. Jana *et al.* [63] developed ZnO/Ni(OH)₂ composite via a polyvinylpyrrolidone and dopamine (PVP -DA) assisted hydrothermal method, which showed a low overpotential of 170 mV @ 10 mA cm⁻² in alkaline solution. Notably, the current density increased during the first 4 hours due to the generation of oxy(hydroxide) real active species. During OER, some irreversible/reversible reactions were found to occur on the surface of the catalyst due to the harsh condition on the anode side. As a result, the real active species could be generated after surface evolution or self-reconstruction during the oxidation reaction [64]. Similarly, the generation of oxy(hydroxide) active species during OER has also been reported by Yuan *et al.* [65]. It revealed that hybrid NiFeOOH/NF electrode had exceptional performance in the alkaline solution by using cell voltages of 1.51 and 1.55 V at 0.5 and 1 A cm⁻², respectively. Herein, the active Fe-OOH and Ni-OOH phases involved in the OER process were identified by using *in situ* electrochemical Raman spectroscopy. According to the XPS analysis results, the oxidation state of Ni was altered from Ni²⁺ to Ni³⁺ during the OER reaction, indicating that NiOOH acted as active centers for OER. In addition, the experimental results from Babar *et al.* [66] reported that the NiFe-OOH/NF electrode had a higher performance than NiFe-OH/NF electrode. Particularly, the NiFeOOH/NF electrode reached 0.4 A cm⁻² at 280 mV, 10 times greater than that of NiFe-OH/NF electrode (40 mA cm⁻²).

Moreover, the overpotential exhibited negligible change after continue the reaction for 75 h at 50 mA cm⁻², indicating its high mechanical robustness. Herein, the nanosheet NiFeOOH electrocatalysts enhanced the catalytic performance due to the metastable structure and long-range disorder atomic arrangement with rich defects and vacancies including void spaces, cation and anion vacancies and cluster gaps, which are advantageous for rapid diffusion of protons and fast transferring of charge. In addition, the abundant intrinsic defects generated by those randomly oriented bonds with high-energy can promote the adsorbing of intermediates on the surface of catalyst, and the amorphous structure's high flexibility can effectively improve electrocatalytic performance [66].

1.3.2 Transition metal layered double hydroxides (TM-LDHs)

Transition metal layered double hydroxides (TM-LDHs) have a basic formula of $[M_{1-x}^{2+}M_x^{3+}(OH)_2]_x^+(A^{n-})_x/n \cdot mH_2O$, where M^{2+} represents a bivalent, M^{3+} represents a trivalent TM cation and A^{n-} refer to charge balancing anion [67]. TM-LDHs like NiCo-LDH, NiFe-LDH, NiMn-LDH and NiV-LDH always have a flexible open structure with chemical versatility and remarkable electrocatalytic properties, which are commonly used as an electrode for water electrolysis. For example, 2D ultrathin nanosheet NiCo-LDH/NiCoS was synthesized via a MOF-involving sulfidation [68]. The synthesized electrode exhibited a low overpotential of 308 mV@0.1 A cm⁻² with a low Tafel slope (48 mV dec⁻¹) value in alkaline solution. The hybrid arrays with rich interfaces between NiCo-LDH and NiCoS can promote the generation of oxygen containing intermediates, accelerating OER kinetics, thereby allowing this electrode to operate for 25 h without degradation. Herein, the *in situ* growth technique can minimize charge transfer resistance, provide more active sites and improve the interactions among solid, liquid and gas phases on the electrode surface, thereby increasing OER activity.

Currently, many studies on the modified TM-LDHs for seawater electrolysis have recently been reported. For example, Strasser *et al.* [69] firstly reported that NiFe-LDH electrocatalyst should meet the above alkaline design criterion. As a result, it achieved a high Faradaic efficiency of ~100% for OER in imitated seawater solution (0.1 M KOH+0.5 M NaCl ; pH = 13) [69]. Dong *et al.* [70] used a mild chemical technique to produce NiFe-LDH on O₂-plasma-treated carbon cloth (NiFe-LDH/CC). This electrode required a low overpotential of 252 mV @ 0.1 A cm⁻² in alkaline solution, which is inferior than that of commercial RuO₂ for OER. It is considered that such a high OER activity should be attributed to partial redistribution among Ni and Fe atoms caused by bridging O²⁻, resulting in the formation of rich active sites, which can facilitate electronical transferring and improve the adsorption/desorption capacity of oxygenated intermediates on the surface of catalyst. As a result, there was no chlorine detected during the reaction, suggesting CIER was completely suppressed by strong interaction between NiFe-LDH and carbon cloth (CC) substrate. Besides, NiFe-LDH/CC maintained its initial potential for 450 and 165 hours for fresh water (pH = 13.8) and seawater (pH = 13.5) based electrolytes at a current density of 0.1 A cm⁻², respectively. Cheng *et al.* utilized CoFe-LDH/Ti for seawater electrolysis (pH = 8.0). This electrode require an overpotential of ~530 mV@10 mA cm⁻² for OER [71]. Liu *et al.* [72] modified CoFe-LDH with a high-valence state of Zr⁴⁺, which improved the electronic structure, optimized the O intermediates, increased the electrochemical active surface area and reduced crystallinity, allowing the low overpotential as 159 and 233 mV at 10 mA cm⁻² for HER and OER in alkaline electrolyte, respectively. Furthermore, in alkaline imitated seawater (1 M KOH+0.5 M NaCl), this catalyst needed a low overpotential of 303 mV @ 0.1 A cm⁻². You *et al.* [73] also found that doping Ir into Ni(OH)₂ remarkably changed the electron density of Ir and Ni sites, accelerating the

generation of $\cdot\text{O}$ and $\cdot\text{OOH}$ intermediates, thereby resulting in a high seawater splitting performance. In alkaline seawater, the monolayer NiIr-LDH worked stably for 650 hours at 0.5 A cm^{-2} without noticeable change with $\sim 99\%$ Faradaic efficiency, indicating that it is applicable for large-scale application. Moreover, multimetallic LDH (NiFe-CuCo-LDH) was proposed as a potential candidate for highly efficient seawater oxidation (e.g., for 6 M KOH seawater electrolyte), which required overpotentials of 259 and 283 mV at 0.1 and 0.5 A cm^{-2} , respectively. This electrode exhibited high OER selectivity (97.4 % Faradaic efficiency for O_2 production at 500 mA cm^{-2}) and good durability for 500 hours in 6 M KOH electrolyte at 0.5 A cm^{-2} [74].

1.3.3 Spinel family

In a spinel oxide with a formula of AB_2O_4 (A, B = Fe, Co, Mn, Ni, Cu, etc.), A is a divalent cation at tetrahedral sites, B is a trivalent cation at octahedral sites and O is an anion. Spinel oxide's crystal structure is made up of metallic ions in tetrahedral and octahedral site centers and oxygen anions arranged at the polyhedral vertexes. Spinel oxide-based electrocatalysts are widely used due to their controllable composition, structure, valence, and morphology. Especially, this structure provides surface redox centers for oxygen adsorption, which is beneficial for OER [75]. Notably, the metal cation in the octahedral site plays a crucial function for OER because of substantially overlapping of highly layered 3d orbital in the octahedrally coordinating metal ions with an O 2p orbital and the weakly overlapped 3d orbital in the tetrahedrally coordinating metal ions with an oxygen atom. Furthermore, the surface of octahedral cation is more easily exposed, implying that it is easier to contact with the reactants [76, 77]. In addition, spinel compounds are excellent electrical conductor with active sites and stable in base solution at a high potential [78]. Generally, multimetallic spinel oxides (MFe_2O_4 ; M = Co, Ni, Cu, etc.) have higher OER activity than monometallic one [79].

Among spinel oxide family, cobalt-based binary spinel-type metal oxides such as MnCo_2O_4 , CuCo_2O_4 , NiCo_2O_4 , etc., have been proposed for OER owing to their redox stability and synergistic interaction between the metal species and mixed variance states of metals. It was discovered that the distribution balance of $\text{M}^{3+}/\text{M}^{2+}$ species in octahedral and tetrahedral sites as well as bond strength between M and oxygen atoms can control active sites [80]. For example, Li *et al.* [81] reported that spinel Co_2MnO_4 had low activation barrier comparable to IrO_2 benchmark due to the ideal binding energies of oxygen evolution reaction intermediates. Moreover, it is found that this catalyst can suppress the catalyst dissolution during long-term operation for over 1,500 hours at 200 mA cm^{-2} .

However, some spinel oxides such as MnCo_2O_4 have low electrical conductivity. To solve this issue, various strategies such as hetero-atom doping, incorporation of O vacancy and deposition of it on the conductive material have been considered. For example, Yang *et al.* [82] found that MnCo_2O_4 -rGO nanocomposites generated from bimetal-MOFs had a low onset potential of 1.56 V *vs* RHE with high electron transfer number, which is comparable to that of Pt/C [82]. Bahadur *et al.* [83] also sulfurized CoMn_2O_4 to improve electrical conductivity and to lower the oxidation state of cobalt, leading to excellent activity and stability with a low overpotential of 300 mV@10 mA cm^{-2} . Wang *et al.* [84] improved the conductivity and ion diffusion rate of cobalt ferrite (CoFe_2O_4) by incorporating NiO. In alkaline solution, the obtained NiO- CoFe_2O_4 /NF electrode required only a low overpotential of 157 mV@10 mA cm^{-2} . Herein, the outstanding OER activity can be attributed to the presence of bimetallic active sites of CoFe_2O_4 and NiO. Wen *et al.* [85] recently immobilized iridium-single atoms (Ir-SAs) in spinel $\text{Ni}_x\text{Mn}_{3-x}\text{O}_4$ for alkaline seawater electrolysis. At 0.1 and 0.2 A cm^{-2} , this electrocatalyst achieved low overpotentials of 330 and 350 mV, respectively. Herein,

the immobilized Ir-SAs not only improved the intrinsic activity, facilitated surface charge kinetics and stabilized *OOH intermediate but also destabilized chloride ions adsorption on the electrode surface.

1.3.4 Transition metal sulfides (TMS)

Transition metal sulfides (TMS)-based electrocatalysts have been investigated for water electrolysis, especially for OER due to their distinctive structure with abundant exposed active sites, high activity, high conductivity and excellent durability. There are distinct classes of TMSs including layered TMS (MS_2) and non-layered TMS (M_xS_y). Corresponding to the periodic table, TMSs in groups 4-7 ($\text{M}=\text{Mo}, \text{W}, \text{Mn}, \text{Nb}, \text{etc.}$) always crystallize with a graphite-like layered structure where as TMSs in groups 8-12 ($\text{M}=\text{Fe}, \text{Co}, \text{Ni}, \text{Zn}, \text{etc.}$) crystallize as a non-layered structure. The different configurations could affect the electronic and electrochemical properties [19]. Generally, the layered ones can be employed as excellent HER electrocatalysts because of their well-exposed edge sites with high electrical conductivity and high intrinsic activity. While, the non-layered ones are effective for OER. Generally, the basal plane and edge plane of the layered TMS have anisotropic properties. The in-plane electrical conductivity of layered MS_2 is approximately 2200 times higher than that of the interlayer one, while the edge plane contributes to fast electron transfer, resulting in an improved electrocatalytic performance [86, 87]. Among TMSs, Ni/Fe-based ones such as NiS and FeS are more efficient for overall water splitting. For instance, Zhang *et al.* [88] reported that the FeS/NiS *in-situ* growing on the nickel foam exhibited low overpotentials of 144 and 203 mV at 10 mA cm^{-2} in 1 M KOH solution for HER and OER, respectively. According to the high conductivity of FeS and NiS with the high active surface area, only a cell voltage of 1.618 V@ 10 mA cm^{-2} was required for overall water splitting. Pan *et al.* [89] enhanced the performance of layered MoS_2

catalyst by covalent Ni and P doping into 1T-enriched MoS₂. By this way, it efficiently activated the basal planes, expanded the interlayer spacing, and increased the edge density of MoS₂ in 2D nanostructure. Moreover, ternary and quaternary non-layered TMSs such as Ni-Co-S, Fe-Co-S and Ni-Fe-S with higher electrical conductivity and faster redox reactions also exhibited excellent activity [90]. For example, Li *et al.* [91] successfully synthesized 3D trimetallic sulfide FeCo₂S₄-NiCo₂S₄ on the Ti mesh. This electrode exhibited a low overpotential as 230 mV at 10 mA cm⁻² for OER. Herein, the synergistic between FeCo₂S₄ and NiCo₂S₄ can significantly facilitate the charge transfer whereas the NiCoFe-S formation results in abundant active sites and increased conductivity. Notably, for the TMSs, there are many strategies such as modification with transition metal based oxides, heteroatomic doping and edge sites engineering to expose more active sites, thereby improving intrinsic activity. For example, Ghouri *et.al.*[92] synthesized hybrid graphene MnFeCoO₄/Mn₂S₂(CO)₇ by a one-step hydrothermal way, which displayed good performance with a low overpotential as ~310 mV at 10 mA cm⁻² toward OER in neutral seawater solution (1 M PB + 0.6 M NaCl, pH 7.0). Chen *et al.* [93] applied a one-step calcination step to dope N anions on Ni₃S₂ (N-Ni₃S₂/NF). To achieve a current density of 0.1 A cm⁻², the prepared electrode needed a low overpotential of 330 mV. Herein, the introduction of N anions can improve electrical conductivity, optimize hydrogen and water adsorption energies, and increase abundant active sites, resulting in high activity as well as durability.

Many reports have mentioned that TMSs are unstable at an oxidizing potential and easily converted to oxides/(oxy)hydroxide during the OER process. Surprisingly, the post-oxidized catalyst is more stable with higher catalytic activity than the initial fresh catalyst [94]. For instance, Hu *et al.* [95] mentioned that FeCo₂S₄/NF electrode required only 290 mV@100 mA cm⁻² due to formation of CoFe-(oxy)hydroxides layer on the

surface, which acted as a real active species, leading to high activity and stability. Yang *et al.* [96] also reported that Ni(Fe) OOH-FeS_x electrocatalyst displayed excellent activity with a low overpotential of 220 mV@10 mA cm⁻². Herein, the incorporation of Fe-S on the Ni(Fe)OOH can strengthen the bond between Fe and the active *O intermediate, which is the rate-controlling step, and significantly reduce the adsorption free energy gap.

1.3.5 Transition metal phosphides (TMPs)

TMPs always demonstrate excellent OER performance owing to the high conductivity, corrosion resistance and catalytic activity. Recently, TMPs have received more attentions because they have shown excellent properties and high durability for seawater electrolysis application. For instance, Ren *et al.* [48] proposed a Ni₂P-Fe₂P/NF electrode for alkaline seawater splitting, which required only low overpotentials of 305 and 431 mV at 0.1 and 1 A cm⁻², respectively. Such a bimetallic phosphide with a high transfer coefficient always performs a phase transformation during OER to form Ni/Fe oxide/hydroxide phases on the surface, which can optimize adsorption intermediates. While, alloying Ni and Fe with P atoms improved the corrosion resistance in seawater solution. Yang *et al.* [50] designed iron and phosphor dual-doped nickel selenide (Fe,P-NiSe₂ NFs) for seawater electrolysis. Herein, doping with Fe cations increased OER selectivity and faradaic efficiency whereas doping with P anions improved the conductivity and prevented catalyst dissolution during long-term operation by generating a passivation layer containing P-O species. In a natural seawater electrolyzer, this catalyst required only 1.8 V@0.8 A cm⁻² and worked consistently for over 200 hours [50]. Qi *et al.* [97] fabricated NiFeP/P-rGO on the nickel foam, which displayed a low overpotential of 290 mV@100 mA cm⁻² with a Tafel slope of 71.9 mA dec⁻¹ in seawater solution (1 M KOH+1 M NaCl). In addition, this catalyst exhibited high durability for

more than 450 hours at 35 mA cm^{-2} without current loss. Herein, the highly active NiFeP and conductive rGO could be responsible for the high activity and stability.

1.4 Bifunctional electrocatalyst design for overall water splitting

Designing bifunctional electrocatalysts for overall water especially seawater splitting is difficult because most electrocatalysts can be only effective at anode or cathode. Recently, some bifunctional electrodes were developed for overall water seawater splitting in various conditions.

1.4.1 Transition metal sulfide (TMS) based electrocatalysts

Transition metal sulfides (TMS) based electrocatalysts could be applied as the bifunctional electrocatalysts for overall water especially seawater electrolysis. For example, Zhao *et al.* [98] revealed that $\text{Ni}_3\text{N}/\text{Ni}_3\text{S}_2$ should be a promising candidate for large-scale water/seawater electrolysis due to the existence of interfacial NiNS between $\text{Ni}_3\text{N}/\text{Ni}_3\text{S}_2$ which can act as the real active species for accelerate dissociative adsorption water molecule, resulting high overall catalytic activity as the bifunctional electrocatalysts. Li *et al.* [99] synthesized Ni_3S_2 -1 T-MoS₂- Ni_3S_2 multi-layered electrocatalyst coated on Ni foam substrate using a two-step hydrothermal process, which required a stable cell voltage of $1.82 \text{ V @ } 100 \text{ mA cm}^{-2}$ for 100 hours in an electrolyte solution containing 1 M KOH + seawater. Herein, the Ni_3S_2 sandwiched structure provided a protective layer against chloride anions, enhancing the durability of this electrode. While, the MoS₂ interlayer can improve electrocatalytic performance [99]. Wang *et al.* [100] fabricated S-NiMoO₄@NiFe-LDH core-shell structure on the Ni foam, in which the NiFe-LDH and S-NiMoO₄ are beneficial for OER and HER in imitated alkaline seawater, respectively. By using this bifunctional electrocatalyst, the two-electrode cell needed a voltage of $1.68 \text{ V @ } 0.1 \text{ A cm}^{-2}$. Seenivasan *et al.* [101] mentioned that multimetallic transition metal sulfide-based electrocatalyst such as

NiCo₂S₄/NiMo₂S₄/NiO (NCMS/NiO) can effectively against chloride corrosion without hypochlorite formation under seawater electrolysis because dual active sites of M-S and M-OOH have remarkable corrosion resistance to chloride ions during seawater electrolysis.

1.4.2 Transition metal phosphide (TMP)-based electrocatalysts

Transition metal phosphide (TMP)-based electrocatalysts could be also utilized as the bifunctional electrocatalysts for overall water splitting especially for seawater splitting. For example, a heterogeneous bimetallic phosphide of Ni₂P-Fe₂P supported on NF represented excellent electrocatalytic activity and durability for overall seawater splitting, which required only ~ 1.81 and 2.00 V cell voltages at 0.1 and 0.5 A cm⁻² in alkaline seawater, respectively. Herein, the heterointerfaces between two phases can improve exposed active sites, thereby enhancing intrinsic activity as well as corrosion resistance [48]. Chang *et al.* [102] doped Fe and P on the nickel selenide (Fe, P-NiSe₂) to improve the electronical structure and surface composition, resulting in increased activity as well as stability over 200 hours in natural seawater electrolysis. Wang *et al.* [103] doped Co on the Fe₂P electrocatalyst (Co-Fe₂P) to change the electronical structure of P for making it more negatively charged, which especially improved HER activity by making it easier to attract protons during HER. As a result, a cell with this bifunctional electrocatalyst (Co-Fe₂P // Co-Fe₂P) showed excellent activity with a cell voltage of 1.69V@100 mA cm⁻² for overall seawater electrolysis. Liu *et al.* [47] synthesized CoNiP/Co_xP composite bifunctional electrocatalyst on NF (CoNiP/Co_xP/NF) by combining electrodeposition and chemical vapor deposition technique, which showed a strong corrosion resistance and abundant exposed active sites, allowing for better catalytic performance and durability for long-term operation. According to the DFT calculations, such a catalyst (CoNiP) has optimal thermodynamic

properties for hydrogen desorption/adsorption, accelerating water dissociation.

1.4.3 Transition metal nitride (TMN) based electrocatalysts

Recently, transition metal nitrides (TMNs) have been reported as the bifunctional electrocatalysts for overall seawater electrolysis application because their high corrosion-resistance, high electrical conductivity and strong mechanical property [104]. For example, the obtained NiMoN@NiFeN core-shell structure required low cell voltages of 1.608 and 1.709 V at 0.5 and 1 A cm⁻², respectively, in alkaline seawater solution [105]. Li *et al.* [106] successfully synthesized NiCoN for HER and NiFeN nanosheets for OER anchored on NiTe nanorod arrays by electrodeposition followed by nitridation. The two-electrode cell (NiTe-NiCoN(-) || NiTe-NiFeN (+)) required only a voltage of 1.84 V@0.5 A cm⁻² for overall seawater splitting.

Table 1.2 Summary of recent studies on the electrocatalysts for HER in alkaline freshwater and alkaline seawater solutions

Catalyst	Electrolyte	η (mV@ mA cm ⁻²)	Durability (h)	Ref.

1.5 SUBSTRATE FOR SUPPORT ELECTROCATALYST

For the large-scale application, the uniformity, accuracy, precision and preparation cost of electrocatalysts need to be considered. There are various techniques to prepare the electrode, which can be divided into two main groups: (i) Preparing of powder-state electrocatalysts and subsequently coated them on current collector (e.g., glassy carbon, NF, and carbon fiber paper) applying a Nafion solution as the binder to enhance electron transportation, and (ii) Binder-free electrode, in which the substrates such as porous metal foam (Ni/Cu foam), carbon paper, carbon cloth, FTO, Ti-foil, etc are always used to replace glassy carbon. In general, by using the binders, it is not suitable for long-term operation because of the deterioration of mechanical strength, electrical conductivity and catalyst peeling-off during a long-term operation [132]. Therefore, directly growing of the electrocatalysts on the substrate is more attractive to prepare the electrode, which is also simple, low cost and reproducible [114]. In this case, it is important to select suitable substrate. In the following, two typical substrates are introduced.

1.5.1 Carbon fiber paper (CP)

Commercial carbon fiber paper is one of the suitable carbon substrates for water splitting application because it has high conductivity, chemical tolerance in acidic/alkaline environments, large surface area and high non-Faradaic background current [133]. Many studies used the carbon paper (CP) as the substrate to improve electrocatalytic performance. For instance, Xiong *et al.* [134] applied a hydrothermal process to synthesize Ni-Mo bimetal sulfides on Co₃O₄/carbon fibers (Ni-Mo-S@Co₃O₄/CF). At 10 mA cm⁻², this electrode displayed a small overpotentials of 85 and 275 mV for HER and OER, respectively. Herein, the 3D hybrid hierarchical heterostructure on CF can be directly connected to the active materials, confirming good electrical conductivity and mechanical stability. A two-electrode cell by using it

demonstrated excellent overall water splitting with a low cell voltage of 1.57 V@10 mA cm⁻², as well as excellent durability and stability for 50 hours without noticeable change. Ye *et al.* [135] supported 3D Co-Fe oxide nanoarrays on the carbon fiber paper (Co_xFe_{3-x}O₄ /CFP) via a facile hydrothermal method, then calcined it in air at 350°C for 2 h. Because of the microporous structure of CFP with high electrical properties, this electrode showed an excellent OER activity and stability, especially at high current density (> 0.5 A cm⁻²).

1.5.2 Nickel foam (NF)

NF is extensively utilized as an electrode support material since it has a large surface area and continuous highly conductive 3D network, which helps to improve electrocatalytic performance [136]. For example, Hao *et al.* [137] prepared FeO_x-Ni₃S₂ on the NF by a one-pot solvothermal reaction, which exhibited a low overpotential of 120 (at 50 mA cm⁻²) and 470 mV (at 200 mA cm⁻²) for HER and OER, respectively in alkaline simulated seawater (1 M KOH + 0.5 M NaCl) since the self-supporting configuration achieved a large catalytic specific surface area of nanosheet arrays as well as fast charge transfer capability. Nowadays, *in situ* growing of electrocatalyst on NF substrate is becoming more popular because it can effectively reduce the resistance between the electrocatalyst and substrate, leading to better electrocatalytic performance with a longer stability. For example, Chen *et al.* [138] synthesized FeIr alloy on NF by using a hydrothermal process at 180°C for 12 h. As it was used as a bifunctional electrocatalyst for overall water splitting at a high current density, low overpotentials of 25.6 and 220 mV at 10 mA cm⁻² were required for HER and OER, respectively. For overall water splitting, it required only a cell voltage of 1.51 V@10 mA cm⁻². Moreover, this electrode showed excellent durability for 124 hours even at 1 A cm⁻² in alkaline solution. Herein, the excellent activity and durability are related to self-supported

volcano-like FeIr alloy on NF, which can significantly enhance intrinsic activity and increase the specific surface. Shin *et al.* [139] successfully synthesized binder-free Fe-Ni hydroxides on NF by a simple corrosion engineering way using a piranha solution (H_2SO_4 and H_2O_2) containing Fe^{3+} precursor, by which the porosity and electrocatalytic active surface area of the electrode were effectively increased while the charge transfer resistance was reduced. Hence, this electrode maintained the OER overpotential as low as 267 mV for 500 h, indicating excellent stability.

1.6 ELECTROCATALYST PREPARATION METHODS

There are numerous methods for growing electrocatalysts on the substrates with excellent performance for water splitting application.

1.6.1 Hydrothermal synthesis method

The hydrothermal synthesis method is a low temperature preparation method that has been generally used for the preparation of metal nanoparticles, metal alloys, metal oxides, and chalcogenides with controllable size, shape, and nanostructure. Herein, the morphology of nanoparticles by using this method could be determined by (i) film rigidity of reverse micelle in microemulsion, (ii) the kinetics of crystal growth in a constrained environment, (iii) the water to surfactant molar ratio, (iv) the intermicellar exchange rate, (v) the organic solvent, surfactant, and co-surfactant, and (vi) the packing parameter [140]. The various morphology, physical properties and catalytic activity could be achieved by using this method. For example, Marimuthu *et al.* [141] fabricated Cu_2S thin film by using a hydrothermal synthesis method at 80°C at different reaction periods. The obtained Cu_2S grown for 1 hour exhibited a lowest overpotential as 76 mV at 10 mA cm^{-2} . Yu *et al.* [105] synthesized highly uniform NiFeN nanoparticles on NiMoN nanorods (NiMoN@NiFeN) by a hydrothermal synthesis method at 150°C for 6 h followed by a nitridation process in a tube furnace, which

exhibited low cell voltages of 1.608 and 1.709V at 0.5 and 1 A /cm², respectively, for overall seawater electrolysis (60°C).

1.6.2 Chemical bath deposition (CBD) method

Zou *et al.* [142] reported an ultrafast strategy for growing other Ni-based bimetallic hydroxide (Ni–M–OH, M = Ni, Fe, Co, Mn, or Cr) films on Ni₃S₂/NF using a chemical bath deposition method. Herein, *in-situ* growing of amorphous Ni-Fe-OH on conductive Ni₃S₂/NF was successfully realized by using a liquid solution containing Fe³⁺ ion at 100°C for 5 s. The obtained electrode exhibited excellent activity and stability for OER at large current densities. Lu *et al.* [143] also proposed a fast sulfurization method to synthesize Ni-CoCHH/NF-S by using Na₂S at room temperature. The obtained electrode displayed an overpotential as 100 mV@10 mA cm⁻² in alkaline solution for HER with almost no change for 25 h.

1.6.3 Chemical vapor deposition (CVD)

Chemical vapor deposition (CVD) is commonly used for preparation of self-standing electrode by deposition of solid compounds onto the substrate's surface. Herein, the key factors for controlling the composition and morphology of electrocatalyst include precursor type, gas flow rate, temperature and pressure [144]. For example, Yang *et al.* [145] prepared Ni@NiO core-shell structure on graphite using a one-step chemical vapor deposition from Bis(cyclopentadienyl)nickel(ii) (NiCp₂) precursor. It is found that the deposition temperature could control the thickness of the graphite layer as well as the Ni content. This special core-shell microstructure displayed an overpotential of 330 mV@10 mA cm⁻² for OER.

1.6.4 Electrodeposition

The electrodeposition technique has been applied for more than two centuries [146], which is one of the most time-saving techniques to synthesize the electrocatalyst with

a high performance [147]. The concept of electrodeposition starts from the reactants which are firstly dissolved in the electrolyte. Then, the oxidized and reduced products can be constantly loaded on the substrate surface by tuning the applied potential. The potential at the working electrode is usually monitored by using a reference electrode. The deposition potential and current, time, pH, temperature and additive are the important parameters for determining size and morphology of the obtained electrocatalysts [148]. Such a method can be used for the synthesis of TM alloy, TM oxides, LDH, TM sulfides and so on. For example, NiO, CuO and Co₃O₄ can be synthesized through electrochemical reduction of NO₃⁻ at first in order to produce hydroxide precursors, which are further annealed to get transition metal oxides [149]. Herein, the main factors influencing electrode structure are metal salt concentrations, applied potential, applied current and time. However, it could be a high electrical energy consumption process.

1.6.5 Aerosol-spray-assisted method

Kuai *et al.* [150] reported an aerosol-spray-assisted approach (ASAA) for producing amorphous mixed-metal oxides for OER. This method allows not only for control size of catalyst and composition but also use of low-cost inorganic salts as the precursor, which is economically applicable for a large-scale electrode production. They obtained Fe₆Ni₁₀O_x electrocatalyst by this method, which showed a low overpotential of 286 mV @ 10 mA cm⁻² for OER. This is the best electrode among Fe-Ni-O_x series. El Emam *et al.* used such an aerosol spray drying method to dope Ni onto BaTiO₃ hollow spheres (HS)/RGO. The charge transfer resistance was lowest in Ni doped BaTiO₃ HS/RGO, indicating improved electrocatalytic activity toward water oxidation [151].

1.7 KEY PARAMETER RELATED TO REACTION KINETIC

For water splitting, there are many parameters such as operation temperature, type of electrolyte, pH, and applied current, which will affect the activity and durability of electrolysis cell. Therefore, it is necessary to consider the optimum conditions to achieve the best electrocatalytic efficiency.

1.7.1 Temperature

Water electrolysis systems can be classified into two categories based on their operating temperatures: (i) low temperature electrolysis system (below 100°C) such as Proton Exchange Membrane Electrolysis Cell (PEMEC) and Alkaline Electrolysis Cell (AEC) and (ii) high temperature electrolysis system (500-900°C) such as solid oxide electrolysis cell (SOEC). On a practical or industrial scale, it should consider whether the system could be operated at a higher temperature to demonstrate the mechanical robustness of the electrode [152].

1.7.2 Electrolytes

Because proton or hydroxide ions must pass through the electrolyte during the water electrolysis process to enable electrochemical reaction at the electrodes, electrolytes are one of the important parameters that affect the electrocatalytic performance. Because of high proton concentration in the acid solution, HER is more kinetically favorable in it. However, OER prefers to occur in the alkaline electrolyte. Thus, the pH value needs to be considered for calculating the overpotential using the Nernst equation as below[153, 154]:

$$E_{eq} = E^0 + \frac{RT}{nF} \ln \left(\frac{a_o}{a_R} \right) \quad (\text{Eq.32})$$

where E_{eq} represents the equilibrium potential, R represents the universal gas constant, T represents the temperature, and a_i represents the activity of species i . When Equation (32) is utilized for HER and OER under standard condition, the equilibrium

potentials (E_{eq}) can be obtained on the standard hydrogen electrode (SHE) as following (33)-(34):

$$HER : E_{eq} = -0.059 \times pH \quad (\text{Eq.33})$$

$$OER : E_{eq} = -0.059 \times pH + 1.23 \quad (\text{Eq.34})$$

Therefore, the equilibrium potentials for HER and OER on the reversible hydrogen electrode (RHE) scale are 0 and 1.23 V, respectively.

1.7.2.1 Acid electrolyte

The acidic condition is commonly used for proton exchange membrane (PEM) electrolysis, particularly for HER, due to its high energy efficiency as well as high hydrogen production rate. Herein, the abundant protons in the acidic electrolyte allow H^+ adsorption on the electrode surface for Volmer reaction, which is beneficial for HER. However, most efficient catalysts for OER are unable to withstand in the acidic condition. For the acidic solution, sulfuric acid (H_2SO_4) and perchloric acid ($HClO_4$) are commonly used, and the pH value of acidic solution is about 0-4 such as 0.5 M H_2SO_4 solution (pH = 0.3) [155].

1.7.2.2 Neutral electrolyte

In neutral or near-neutral condition, 0.1 M Na_2SO_4 or 0.1M $KClO_4$ is usually used to evaluate the water electrolysis performance at pH=7. However, phosphate-buffered saline (PBS, pH ~7), carbonate buffer (CBF, pH~8.6-10.6) or borate-buffered saline (BBS, pH ~8.5-9.2) is generally used for the evaluation of the electrocatalysts working at neutral or near-neutral condition for water splitting. For proton generation, the HER rate, which is determined by the pK_a of the buffering species and the pH of a solution, most likely acts as a proton carrier and directly involved in surface reactions [156]. Similarly, the presence of buffered species can improve the reaction rate of OER by facilitating the removal of generated proton on the electrode surface [157]. In this case,

due to the lower proton/hydroxyl concentration in the solution, the OER has slower kinetics in this condition when compared to alkaline or acidic conditions.

1.7.2.3 Alkaline electrolyte

Alkaline electrolyzer always operates under potassium hydroxide (KOH) or sodium hydroxides (NaOH) containing solutions. Because of its higher conductivity, KOH solution is more commonly used than NaOH to adjust the pH of the electrolyte. The molar ion conductivities of Na^+ , K^+ , and OH^- are 0.050, 0.073, and 0.198 $\text{S L mol}^{-1} \text{ cm}^{-1}$, respectively [60]. Generally, the pH of alkaline aqueous solution used in alkaline water splitting ranges between 11 and 14, depending on the molar concentration of KOH or NaOH solution [7].

1.7.2.4 Simulated seawater electrolyte

Addition of 0.5 M NaCl into 1 M KOH solution is usually used for simulate seawater condition since this NaCl concentration is almost the same as that in natural seawater [105, 122, 125]. Moreover, the pH of alkaline imitate seawater solution is about 13-14. In addition, Juodkazytė *et al.* [122] also mimicked the seawater solution by mixing a solution containing 27.495 g NaCl, 6.912 g MgSO_4 , 1.1 g CaCl_2 and 0.745 g KCl and 1,000 ml of deionized water with 1.0 M KOH to obtain actual concentrations of Na^+ , Cl^- , SO_4^{2-} , Mg^{2+} , Ca^{2+} and K^+ close to natural seawater. Herein, adding KOH is one of the pre-treatment steps for seawater without using a membrane because KOH aids in the precipitation of $\text{Mg}(\text{OH})_2$ and $\text{Ca}(\text{OH})_2$, resulting in a clear solution and preventing the catalyst active sites from being blocked [158]. This condition is now widely used as a preliminary step in the development of an electrocatalyst for seawater electrolysis.

1.7.2.5 Natural seawater electrolyte

Natural seawater contains a variety of ions such as Na^+ , Cl^- , SO_4^{2-} , Mg^{2+} and Ca^{2+} , and contaminants, and thus, direct seawater splitting still remains challenge.

The pH of natural seawater is close to a neutral state with pH values ranging between 7.5 and 8.4 [159]. As illustrated in Table 1.6, the majority ions in the natural seawater are Na^+ and Cl^- ions, which could cause electrocatalyst corrosion and deterioration [160, 161]. Thus, the properties of natural seawater will greatly influence the design and operation of water electrolysis process, and sometimes, the pre-treatment process is required before use. There are numerous methods for treating the seawater before it is used as an electrolyte. For example, Zhang *et al.* [162] proposed a hybrid seawater electrolyzer (HSE) that combines seawater electrolysis and sulfion degradation, by which the key development is the reduction of seawater for HER at the cathode while degrading of the sulfion at the anode side, avoiding anode corrosion and Cl^- crossover and allowing fast and efficient degradation of S^{2-} pollutants to sulfur. Sun *et al.* [1] also mentioned that coupling of chlorine-free hybrid seawater splitting with hydrazine degradation can effectively reduce the energy input by 48% while provide high Faradaic efficiency without Cl^- crossover and prevent toxic hydrazine from polluting seawater. In this system, the cathode side is used for HER from seawater while the anode side is supplied with OH^- crossover for hydrazine degradation to reduce salinity, which is separated by an anion exchange membrane (AEM).

The electrolytes used in water water electrolysis cell are summarized in Table 1.7.

Table 1.6 Chemical compositions of natural seawater [160, 161]

Common Name	Elements	Chemical species	Concentration (ppm)
Chloride	Cl	Cl^-	~19500–22014
Sodium	Na	Na^+	~11536–14039
Magnesium	Mg	Mg^{2+}	~1290–1543
Sulfur	S	SO_4^{2-} , NaSO_4^+	~905–3273
Calcium	Ca	Ca^{2+}	~378–420
Potassium	K	K^+	~380–470
Bromine	Br	Br^-	~67

Carbon	C	$HClO_3^-$, CO_3^{2-}	~28
Nitrogen	N	NO_3^- , NH_4^+	~12

Table 1.7 Summary of the electrolytes used in electrolysis cell

Electrolyte	pH
Alkaline solution (1M KOH, 1M NaOH)	14
Simulated seawater solution (1M KOH+0.5M NaCl)	13.8
Borate buffer	9.2
Carbonate buffer	8.6
Phosphate buffer	6.4-7
Acidic solution (0.5M H ₂ SO ₄)	3

1.7.3 Input current

1.7.3.1 Continuous current

Continuous electrochemical water electrolysis is a general process for hydrogen production using a constant current input. Acid and alkaline freshwater solutions are usually used as the electrolyte in this system. However, considering the sustainability, using freshwater with higher cost and scarcity is not recommended. While, using renewable energy based electricity should be a sustainable way for water splitting.

1.7.3.2 Intermittent current or power interruption

Water electrolysis can be electrified by intermittent renewable energy sources like solar and wind powers, which can make hydrogen production more environmentally friendly. However, if the electrolyzer is powered by the intermittent renewable energy, frequent power interruption and shutting downs can hasten electrode degradation [163, 164]. In order to simulate power interruption condition, the chronoamperometric test can be used by setting up the power in an on-off condition and measure the current density with a constant applied potential and comparing with the continuous electrolysis. Herein, the corresponding current density is always recorded to verify the electrocatalysis activity and stability.

1.7.3.3 High current density

For the large-scale water electrolyzer, it is necessary to have highly durable electrocatalysts which can be worked at a high current density above 0.5 A cm^{-2} or 1 A cm^{-2} for alkaline electrocatalytic cells or proton exchange membrane [165, 166]. To date, the majority of reported electrocatalysts have been reported at a relatively low current densities ($< 0.1 \text{ A cm}^{-2}$), which is incompatible with industrial qualification, but only a few works on OER electrocatalysts have been investigated under harsh conditions [167]. Notably, most developed electrocatalysts are always deactivated during the OER process at a high current density. For example, Zhou *et al.* [168] mentioned that the stability of NiFe-LDH on Cu nanowires is not good at a high current density (0.5 A cm^{-2}) under alkaline condition (1 M KOH solution). Gupta *et al.* [169] used a Co-Fe-O-B electrocatalyst for OER in saline water (1 M KOH + 0.5 M NaCl), which exhibited high activity with a low overpotential of $294 \text{ mV}@10 \text{ mA cm}^{-2}$, but the current lost nearly 35% after stability test for 20 hours. Besides, the faradaic efficiency was also reduced from nearly 100% to $\sim 74\%$ due to Cl^- oxidation at a high current density (e.g., 0.1 A cm^{-2}) [169]. Therefore, seeking for a catalyst which can maintain its initial performance for long-term operation at a high current density is greatly desired for the improvement of electrolysis efficiency for large-scale water splitting.

1.8 EVALUATING PERFORMANCE

1.8.1 Electrocatalytic activity

The activity of electrode is generally characterized by determining overpotential, Tafel slope, and exchange current density via the calculations based on the measured polarization curves [170]. The overpotential (η) is defined as the difference between the applied potentials required to deliver a current density and thermodynamic potential value, which is commonly used to estimated the catalytic activity for water splitting

[171]. The equilibrium potentials for HER and OER are known to be 0 and 1.23 V (both vs RHE), respectively. Because of the intrinsic kinetic barrier, an extra potential which is larger than the equilibrium potential is always needed to activate the reactions. Such an extra potential is defined as the overpotential. In general, linear sweep voltammetry (LSV) and cyclic voltammetry (CV) test can be utilized to determine an electrocatalytic activity. A smaller overpotential means higher electrocatalytic activity [94]. Moreover, the overpotential @10 mA cm⁻², which is equivalent to a 10% efficiency of solar-driven water electrolysis, is usually reported as the standard basis for comparison of different electrocatalysts [78].

Owing to the slow kinetics of the four-electron transfer reaction, the OER is the hindrance for scaling-up in a water electrolysis system whereas the HER is just a two-electron transfer reactions. Thus, OER requires more energy (higher overpotential value) to overcome the kinetic barrier [78]. The Tafel slope is an overpotential-dependent criterion, which is associated with catalytic reaction mechanism for both HER and OER in terms of electron-transfer kinetics. The value of Tafel slope refers to certain pathway for the catalytic reaction. As such, if the Tafel slope (mV/decade) is lower meaning that less overpotential is required to get high current and faster kinetics. The Tafel slope can be used to identify the rate-determining step (RDS) for both HER and OER [172]. Theoretically, the Tafel slope for HER is about 40-120 mV dec⁻¹. The rate determining step of the reaction can be determined using the Tafel slope value [173]. The exchange current density (i_0) can be used to explain the intrinsic charge transfer under the equilibrium condition. A greater charge transfer rate and a lower reaction barrier are associated with a higher exchange current density. In conclusion, a superior electrocatalyst should have a lower overpotential, a smaller Tafel slope and a higher exchange current density [170, 174].

1.8.2 Stability

Catalyst stability is an important criteria for predicting potential industrial-scale application. The commercialized electrode must be able to operate for hundreds to thousands of hours or cycles with negligible change [175]. The applied fixed potential and current can be measured using chronoamperometry (I-t curve) and chronopotentiometry (E-t curve) over a period of time to determine the stability. There is no benchmark for the stability test, however, numerous studies have been reported stability for at least 10 h at 10 mA cm^{-2} [170]. For large-scale application, the stability should be maintained over 100 hours at high current densities ($>500\text{-}1000 \text{ mA cm}^{-2}$) [1]. Furthermore, cyclic voltammetry (CV) test with over 5000 cycles, which is also called accelerated degradation test (ADT), is also used to investigate the overpotential gap between before and after the test. Currently, the stability or durability of most electrocatalysts are still not satisfied for the industrial scale application. Kuang *et al.* reported a highly durable electrode for seawater splitting for over 1,000 h in a solar-driven alkaline seawater electrolysis system using the NiFe/NiS_x-Ni electrocatalyst, which is the most longest period of time for the electrocatalysts working in an alkaline seawater solution [125]. Recently, sophisticated *in-situ* techniques has been developed to monitor catalyst dissolution during the long-term operation. For example, electrochemical flow cells or the electrochemical quartz microbalance has been applied for a deeper understanding of catalyst degradation mechanism [176, 177].

1.8.3 Faradaic efficiency

Faradaic efficiency is used to describe the efficiency of electron transfer involved in the reaction for both HER and OER. It can be measured from the amount of gas production during the real reaction obtained from experiment and the calculated amount of gas produced theoretically. Herein, the amount of generated gas H₂/O₂ can be

examined by using gas chromatography (GC) measurement or a water displacing technique. It is reported that the amount of O₂ from OER can be defined by using a rotating-disk electrode (RDE) [94]. Faradaic efficiency can be evaluated from the ratio of experimental gas volume to the theoretical gas volume as shown in the following equation [178, 179]:

$$\text{Faradaic efficiency} = \frac{V_{\text{Experimental}}}{V_{\text{Theoretical}}} = \frac{V_{\text{Experimental}}}{\frac{1}{2(4)} \times \frac{Q}{F} \times V_m} \quad (\text{Eq. 35})$$

where, Q is charge passing through the electrode, F is Faraday's constant (96,485.3 C/mol), the numbers of 2 and 4 indicate mol of electrons per mole of H₂ (for HER) and O₂ (for OER), respectively, V_m is the molar volume of gas (24.5 L/mol, 298 K, 101 KPa). The high faradaic efficiency means that the electrode can be stable against oxidation or reduction for HER and OER, respectively. Therefore, a higher faradaic efficiency means a high catalytic efficiency.

1.8.4 Electrochemical active surface area (ECSA)

The intrinsic activity of the electrocatalyst is able to determine by ECSA normalization without the metal loading effect whereas the geometrical area normalized current density always shows a dependence on catalyst loading [180]. There are several methods to investigate the ECSA of catalyst. However, estimating the ECSA from the double layer capacitance (C_{dl}) using the Cyclic voltammetry (CV) method at various scan rates in non-faradic region is more accurate. In this case, the charging current is plotted at the various scan rates [181], and the ECSA can be evaluated using Eq. 36 [182]:

$$\text{ECSA} = C_{\text{dl}} / \text{CS} \quad (\text{Eq. 36})$$

where, C_{dl} (mF) is double layer capacitance from CV test; CS is the estimated specific capacitance of 0.04 mF cm⁻² in alkaline solution.

1.8.5 Density functional theory (DFT) calculations

To further deep understanding the insight electronic state, coordinate environment of catalytic active sites and catalytic mechanism, density function theory (DFT) calculation is always used [183]. The DFT calculation can understand the adsorption/desorption kinetics, which corresponds to the Gibb's free energies, intermediates during HER/OER reaction, and energy barrier, thereby inferring the rate determining step. Theoretically, HER and OER have different reaction mechanism since HER is a 2-electron pathway while OER involves in a four-electron pathway [96]. Therefore, the water adsorption energy and reaction intermediates are different and OER is considerably more complicated [184]. For HER, if adsorption free energy of H* closes to zero, implying higher catalytic activity. In general, the lower energy barrier means the improved kinetics with higher catalytic activity.

1.8.6 Chlorine Determination

Due to the competitive reaction between OER and CIER in the presence of Cl⁻ in the seawater solution, the formation of hydrochloric acid (HCl) and hypochlorous acid (HClO) as follows becomes possible [185, 186] ;

Ko *et al.*, designed an *in-situ* headspace Cl₂ gas detector that decoupled O₂ and Cl₂ generation from a rotating disk electrode. The concentration of Cl₂ is measured using chronoamperometry test during electrolysis [186]. For two-electrode configuration, Yu *et al.*, used 1M KOH + Seawater as electrolyte using Chronopotentiometry test with a constant current density, then removed the gaseous product with a syringe and injected it into a GC-TCD instrument [124].

1.9 OBJECTIVE OF THIS STUDY

According to the above review, for scaling up the experimental results from lab-scale to industrial-level by using natural seawater as a water resource for water splitting, either the electrocatalytic performance or the catalyst preparation step as well as the cost of chemical substances need to be considered. Therefore, searching for earth-abundant and cost-effective electrocatalysts with high electrocatalytic activity and durability, especially at a large current density for seawater electrolysis is still full of challenges. Besides, to meet the practical industrial-scale requirements, the electrocatalysts should be operated at high current density ($> 500 \text{ mA/cm}^2$) to achieve a high hydrogen production efficiency. Therefore, the objective of this research focuses on developing earth-abundant and low-cost 3D transition metal-based nanostructured electrocatalysts for highly efficient and durable water electrolysis at a high current density for either HER or OER towards an industrial-scale. It is expected to prepare electrocatalysts with a high intrinsic activity with a low overpotential and Tafel slope, high electrical conductivity with fast electron transport properties, low charge transfer resistance, high electrocatalytic active surface area (ECSA), highly durable and close to theoretical Faradaic efficiency for water splitting in various electrolytes as well as input current densities. While, the reaction mechanism and surface adsorption energy on the surface of electrodes were clarified.

1.10 SCOPE OF THIS DESSERTATION

Chapter 1 summarizes the reaction mechanism of water electrolysis, introduces current trends of anode/cathode materials, elucidates the effects of substrate and preparation method on the performance of electrocatalysts, emphasizes key kinetic parameters and performance evaluation procedures. Finally, the objective of this study is given.

Chapter 2 reports that CuVO_x nanobelt@NiO nanosheet with O vacancy-rich composite is successfully coated on the carbon paper by one-pot hydrothermal method followed by calcination. The morphology and oxidation state of prepared electrodes are examined before and after testing. In alkaline solution, the electrocatalytic activity and stability of HER are evaluated. The electrochemical active surface area is also investigated under the same condition. Furthermore, their electrochemical performance is evaluated and compared to a commercial noble metal catalyst.

Chapter 3 introduces that the FeNiS_x/NiFe(OH)_x on nickel foam (NF) is successfully fabricated using a facile corrosion engineering followed by a fast and mild sulfurization process. In the preliminary step, the preparation time and morphology are investigated. The electrocatalytic performance of the obtained electrode is measured in both alkaline and alkaline simulated seawater solutions. The morphological and chemical states of initial and spent catalysts are characterized. The DFT calculations are also performed in order to elucidate OER mechanism and Cl⁻ adsorption energy on the electrode surface. This electrode is also used as a bifunctional electrocatalyst for overall seawater splitting, and its electrochemical performance is compared to a commercial electrode (Pt/RuO₂).

Chapter 4 reports that the NiFe-LDH core @MnCo₂O₄ shell electrocatalyst is fabricated in order to achieve outstanding electrocatalytic performance and corrosion resistance in an imitate seawater solution. It is found that the synergy of a large active surface area, Mn species with Cl⁻ blocking capability, and highly active NiFe-LDH can effectively improve activity and extend stability in chloride-containing solutions. The obtained electrode exhibits excellent catalytic activity for OER with low overpotentials of 219 and 460 mV at 100 and 500 mA/cm², respectively. Furthermore, it can operate for over 25 hours without corrosion in an imitation seawater solution even at a high current density of 1 A/cm² with complete OER selectivity against ClER. Furthermore,

the NiFe-LDH@MnCo₂O₄ can be used as a bifunctional electrocatalyst for overall seawater splitting, requiring only a low cell voltage of 1.54 V at 10 mA/cm² and maintaining its initial potential for 100 hours at a high current density without catalyst degradation and corrosion. Such an electrocatalyst is expected to be a promising candidate for sustaining seawater splitting in an industrial scale.

Chapter 5 summarizes the main results and new finding of this study and future perspective for large scale application is also discussed.

CHAPTER 2 Facile fabrication of O vacancy rich CuVO_x nanobelt@NiO nanosheet array for hydrogen evolution reaction

2.1. Introduction

Hydrogen is regarded as one of clean fuels for a sustainable future. It can be produced from various processes including the thermochemical conversion of organic materials such as fossil fuels and biomass and water electrolysis. In particular, the water electrolysis is a clean way for the pure hydrogen production without direct CO₂ emission [1-3]. The water electrolysis process includes two half electrode reactions, i.e., oxygen evolution reaction (OER) and hydrogen evolution reaction (HER) [4]. For the HER in the alkaline condition, the limitation is the sluggish electrochemical reaction due to the Volmer step for the formation of adsorption proton (H_{ads}) during the water dissociation and the Heyrovsky step for the detaching of hydrogen molecule [5, 6]. In the alkaline electrolyte, the reaction starts from the catalytic cleavage of H₂O molecule into OH⁻ and H_{ads} (Volmer step; $\text{H}_2\text{O} + \text{e}^- \rightarrow \text{H}_{\text{ads}} + \text{OH}^-$), followed by a Heyrovsky step with a hydrogen molecule detached from the surface of catalysts via either the interaction of the H_{ads} atom and H₂O (Heyrovsky/Tafel step; $\text{H}_2\text{O} + \text{e}^- + \text{H}_{\text{ads}} \rightarrow \text{H}_2 + \text{OH}^-$) or the recombination of two H atoms (Tafel step; $\text{H}_{\text{ads}} + \text{H}_{\text{ads}} \rightarrow \text{H}_2$). Thus, it is important to improve both the Volmer and Heyrovsky steps for the enhancing electrocatalytic performance [7].

Currently, noble metal based electrocatalysts (mainly Pt-based ones) are still the most effective catalysts for the HER. However, they are too expensive and too scarce, and especially, their performances are still unsatisfactory owing to their inefficient HO-H

bond cleavage ability, limiting their widespread applications [8, 9]. Nowadays, numerous efforts have been paid to develop high-performance electrocatalysts with low cost. To date, various transition metal oxide based electrocatalysts such as NiO, CuO, V₂O₅, MnO₂, Fe₂O₃, Co₃O₄ and ZnO based ones and their mixtures have been widely studied since their electrocatalytic activities can be effectively improved by controllably adjusting their nanostructures and compositions [10-12]. Meanwhile, bi/tri-metal oxides have been studied as the promising HER electrocatalysts because of the synergistic effect from the formation of special nanostructures, the regulating of electronic structure, the exerting of the intrinsic properties for the enhancing electric/ionic conductivity, the balancing of intermediates adsorption/desorption energy for the hydrogen generation, the promoting of the capability towards the breaking of O-H bond, and/or the increasing of the electrochemical stability [11, 12]. For examples, Hao *et al.* [13] prepared an electrocatalyst of Fe_{1.89}Mo_{4.11}O₇/MoO₂ with a regulated Mo electronic structure, by which a Mo-H bond strength similar to the Pt-H bond strength was exhibited and a fast kinetics for the HER was achieved. Jiang *et al.* [14] doped cobalt on two-dimensional (2D) ceria nanosheets, which effectively promoted the generation of oxygen vacancies on ceria oxide nanosheets for the optimizing of hydrogen binding/water dissociation with the increased active sites, thereby exhibiting an outperformance even over Pt in alkaline HER with long-term durability. Besides, Peng *et al.* [15] found that the super-hydrophilic surface should be also benefit for the catalytic HER since the enhanced contact area between electrode and electrolyte can promote hydrogen desorption from the surface of catalyst.

However, the pure transition metal oxides generally exhibit not so high activity for catalyzing HER due to the unbefitting hydrogen adsorption energy [16]. Especially, although the metal oxide and hydroxide based catalysts are good at the splitting of the

HO-H bonds, they could not efficiently converse the obtained H* intermediates to H₂ [17, 18]. On the other hand, due to their good stability within a wide range of electrochemical window in alkaline solution, considerable efforts have been devoted to overcoming these barriers, and some efficient tactics are developed to synthesize the high active metal oxide based HER catalysts.

Recently, vanadium oxides (VO_x) including VO₂, V₂O₃, V₂O₅, V₂O₇ and V₃O₈ have gained great attention due to their high catalytic activities and excellent electrical properties with outstanding electronic structures, large conductivity as well as high charge transfer capability and multi-valence feature [19]. They have been widely investigated for the applications in lithium batteries and photocatalysis but seldomly considered for the HER since they always have low specific surface area and poor electronic conductivity [14, 20]. It is reported that the introduction of other metals in VO_x could be an effective way to increase the electronic conductivity and stabilize its structure during the redox reaction [21]. For example, Bai *et al.* [22] synthesized CuV₂O₅ via a hydrothermal way, and found that the obtained CuV₂O₅ had good electrical conductivity and structure stability. Meanwhile, it is found that V₂O₅ can reactivate the deactivated Ni cathode in water electrolysis, and based on this finding, Li *et al.* [3] implanted Ni-O-VO_x sites with Cu on the surface of nickel foam (NF) to create a Ni(Cu)VO_x electrocatalysts with excellent HER activity and stability in alkaline solution. Herein, the combination of V and Ni species promoted the charge redistribution from Ni to VO_x, which greatly improved the kinetics for H_{ads} atom and fast release of H₂ from the catalyst surface. Moreover, VO_x resulted in the damper of Ni lattice and the generation of large electrochemically active surface area. Meena *et al.* [23] also prepared V₂O₅/Ni(OH)₂ electrocatalysts on NF (V₂O₅/Ni(OH)₂@NF) for HER in alkaline solution, which showed a Pt-like activity with a overpotential as low as 39

mV @ 10 mA cm⁻² and long-term stability. Herein, assisting by V₂O₅, the near-zero adsorption free energy (ΔG_{H^*}) for H_{ads} atom could be achieved on the active sites owing to the charge transfer resulted from the adsorbed O species on Ni (111) plane together with high conductivity of NF. While, the weak hydrogen binding strength due the downshifting of the d-band center by the O-adsorption on the Ni surface could lead to a favorable kinetics for H_{ads} atom and fast release of H₂ on the surface of catalysts. Similarly, Li. *et al.* [24] used VO_x clusters to modulate a metallic Co catalyst (denoted as Co(VO_x)) for HER, and found that the VO_x clusters can endow Co with a highly disordered lattice and decrease the particle size, and as a result, an optimal doping level of 3% effectively regulated the atomic structure, which not only provided more active sites and reduced the H* binding, but also enabled an efficient electron transferring from Co to VO_x to decrease the H* adsorption on V-Co(001) for enhancing HER.

Besides, defect engineering, e.g., O vacancy generation, is an efficient methodology to boost up the HER activity as well as stability [25]. For example, An *et al.* [26] modified the electronic structure of NiMoO₄ surface by doping N at the NiO₆ sites to concomitantly generate the oxygen vacancy defects by heteroatomic exchange with the electrical neutrality principle between 2N³⁻ and 3O²⁻ species, which led to the formation of multiple active sites with the improved metallic conductivity as well as the lowered adsorption energy barrier of Heyrovsky step. Similarly, Liu *et al.* [27] reported that the introduction of oxygen vacancies in the NiCo₂O₄ material effectively reduced the adsorption energy and dissociation energy barrier of H₂O, which was attributed to the low-coordinated metal sites derived from the oxygen vacancies, thereby promoting the Heyrovsky step of alkaline HER. Meanwhile, Wang *et al.* [28] used iridium (Ir) and ruthenium (Ru) to tune the electronic and atomic structure of NiV layered double hydroxide (LDH) to promote the water electrolysis kinetics, and found that the

synergistic electronic interactions existed among the Ru (Ir), V and Ni cations. Especially, the local coordination environments around the V and Ni cations were modulated, resulting in more V vacancies, which could optimize the adsorption energy of intermediates in the Volmer and Heyrovsky steps for the HER. Therefore, combining of VO_x with other metal oxide and/or metal catalysts could result in some unique atomic structure with more oxygen vacancies, thereby achieving highly catalytic performance for the HER.

Herein, a defect rich CuVO_x nanobelt @ NiO nanosheet composite was synthesized on the pretreated carbon paper (CP) by using a facile hydrothermal process combined calcination method. The obtained CuVO_x-NiO electrocatalysts contained conductive a CuVO_x layer with rich defects and active NiO nanosheets with high wettability, which resulted in favorable kinetics for H_{ads} atom and fast release of H₂ on the surface of catalysts. As a result, this novel CuVO_x-NiO@CP electrode exhibited high activity and stability for HER in the alkaline solution.

2.2 Experimental section

2.2.1 Chemicals and Materials

Ammonium metavanadate (V) (NH₄VO₃, 99%), nickel (II) nitrate hexahydrate (Ni(NO₃)₂·6H₂O, 98%), copper (II) nitrate trihydrate (Cu(NO₃)₂·3H₂O, 98%), nitric acid (HNO₃, 69%), potassium hydroxide (KOH, 85%) and ethanol (C₂H₅OH, 99.5%) were purchased from Wako, Japan. Deionized (DI) water (18.2 MΩ cm) was used to prepare the solution. Carbon paper (CP, TGP-H-060, thickness: 190 μm) was purchased from Toray, Japan.

2.2.2 Synthesis of CuVO_x@NiO based electrode

CuVO_x@NiO composite was directly grown on CP substrate by a hydrothermal process combined calcination method. In brief, a piece of carbon paper (2 x 2 cm²) was

treated in 6 M HNO_3 solution under an ultrasonic condition for 3 h, and then washed with ethanol and DI water consecutively for the removal of those impurities. Meanwhile, the calculated amounts of NH_4VO_3 , $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$, $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, NH_4F and $\text{CO}(\text{NH}_2)_2$ were dissolved in DI water (20 mL) under stirring for 30 min and then, 6 M HNO_3 solution was slowly added into the above solution to adjust pH to 3. Thereafter, the solution was introduced into an autoclave with Teflon-line, in which the pretreated CP was vertically fixed. The hydrothermal reaction was performed at 180 °C for 12 h. Finally, the composite coated CP electrode was washed by ethanol and DI water consecutively for several times, and then dried at 80 °C in a vacuum oven overnight, and finally treated at 450 °C for 3 h with a 2 °C/min heating rate. As such, the $\text{CuVO}_x\text{-NiO@CP}$ electrode was obtained (Figure 2.1). Herein, the chemical composition of $\text{CuVO}_x\text{-NiO}$ was preliminarily optimized based on the HER performance and the molar ratio of Ni:Cu:V with 1:4:2.5 was selected as the optimal composition for further investigation. For comparison, Ni-Cu mixed oxide, Ni-V mixed oxide, Cu-V mixed oxide and pure V_2O_5 were also coated on CPs by the same methodology and conditions.

Figure 2.1 Schematic illustration for the preparation of $\text{CuVO}_x\text{-NiO@CP}$ electrode via a one-step hydrothermal method.

2.2.3 Material Characterizations

Morphology and nanostructure of the as-synthesized electrocatalysts were observed by a scanning electron microscope (SEM, SU8010, HITACHI, JAPAN) and a transmission electron microscope (TEM, JEM-2100F, JEOL), respectively. Crystalline structure of the sample was determined by an X-ray diffraction (XRD, Rigaku Smartlab diffractometer, Japan) measurement in a 2θ range of 10° - 80° using a Cu-K α radiation source ($\lambda = 0.15406$ nm). The contact angle on the electrocatalyst surface was measured by a contact angle meter (DMe-201, Japan) using DI water drop. Raman spectrum was obtained using a JASCO NRS-5100 ($\lambda = 632$ nm). The XPS measurement was performed at ambient temperature on a VG Scientific ESCALab250i-XL XPS machine with an Al-K α X-ray source.

2.2.4 Electrochemical performance tests

Electrochemical performance test was performed on an electrochemical workstation (Versa STAT4, Princeton, USA) with a three-electrode system. A standard Hg/HgO electrode and a carbon rod were used as the reference and counter electrodes, respectively. HER performance of the electrocatalyst was evaluated using a linear sweep voltammetry (LSV) at a scan rate of 1 mV s^{-1} in a potential range of $-0.9 \sim -1.5$ V in 1 M KOH solution. The potential relating to the reversible hydrogen electrode (RHE) was determined by the following equation: $E(\text{RHE}) = E(\text{Hg/HgO}) + 0.098 + 0.059 \text{ pH}$ [29]. LSV polarization curve was recorded with iR-compensation. Meanwhile, EIS (electrochemical impedance spectroscopy) measurement was performed at a frequency range of 100 kHz-0.1 Hz in 1 M KOH solution. The cyclic voltammetry test was carried out in a potential range of -0.2 - 0 V (vs RHE) at a scan rate range of 10 - 100 mVs^{-1} to obtain the electrochemical active surface area (ECSA). The stability test was performed by two methods: (i) chronopotentiometry analysis at 10 mA cm^{-2} for 30 h;

and (ii) cyclic voltammetry analysis at a potential range of 0.1~ -0.3 V (vs RHE) for 1000 cycles.

2.3. Results and discussion

2.3.1 Morphology and structural characterizations

XRD patterns of the synthesized electrocatalysts before the calcination are presented in Figures 2.2(a-c). One can see that all of them show a hydroxide form. For the CuVO_x-NiO@CP before the calcination, Cu₃V₂O₇(OH)₂·2H₂O with hydroxyl groups exist, which can be completely changed to Cu₃V₂O₈ after the calcination at 450 °C based on the following equations;

Figures 2.3 (a-d) displays XRD patterns of CuVO_x-NiO, CuVO_x, V₂O₅ and NiO after the calcination, the characteristic peaks located at 2θ of 37.2°, 43.3° and 62.9° correspond to the (111), (200) and (220) planes of NiO (JCPDS No 71-1179), and the diffraction peaks at 2θ of 26.5°, 32.3°, 36.3, 37.1, 43.2° and 49.2° indicate the formation of monoclinic CuV₂O₅ phase (JCPDS No. 43-0080) while the small diffraction peaks at 2θ between 16.5° and 66.3° match well with those corresponding to the monoclinic Cu₂V₂O₇ (JCPDS No. 73-1032) and Cu₃V₂O₈ (JCPDS No. 74-1503) phases. Herein, in the crystal structures of monoclinic Cu₂V₂O₇ and Cu₃V₂O₈, a Cu atom is coordinated with five oxygen atoms while a V atom with four oxygen atoms forms the VO₄ tetrahedral structure [30]. It should be noted that it is difficult to find the main peak at 2θ of 26.1° corresponding to V₂O₅.

Figure 2.2 XRD patterns of all synthesized electrocatalysts before the calcination.

Figure 2.3 XRD patterns of (a) $\text{CuVO}_x\text{-NiO}$, (b) CuVO_x , (c) V_2O_5 and (d) NiO .

As presented in Figure 2.4a, CuVO_x with a nanobelt structure (Figure 2.4b, thickness: ca. $0.43\ \mu\text{m}$) is formed on the CP with a smooth surface. While, pure NiO with a nanosheet structure (Figure 2.4c) is deposited in the CP. When Cu^{2+} , VO^{3-} and Ni^{2+} ions co-exist in the initial solution, the nanosheets seem to be grown on the nanobelt during the hydrothermal synthesis process, which could be a composite of CuVO_x -NiO formed on the CP (Figures 2.4(d-e)). As illustrated in Figure 2.1, CuVO_x nanobelt seems to be formed on the CP initially, followed by NiO nanosheets growing on the surface of the CuVO_x nanobelt layer. Herein, in the acid condition, the Cu^{2+} and VO^{3-} with higher molar concentrations than Ni^{2+} could react faster to form various compounds such as $\text{Cu}_3\text{V}_2\text{O}_7(\text{OH})_2 \cdot 2\text{H}_2\text{O}$ with the nanobelt structure. In parallel, due to the hydrolysis of urea, Ni^{2+} ions would form $\text{Ni}(\text{OH})_2$ layer anchoring on the surface of CuVO_x . After the calcination, the CuVO_x -NiO composite is generated. One can see that the nanosheet on the nanobelt has a thickness of $0.12\ \mu\text{m}$ (Figure 2.4f). EDS elemental mappings of Ni, Cu, O and V on the surface of CuVO_x -NiO@CP are shown in Figures 2.5(d-h). One can see that the colour intensity of each element is fluctuating with the element concentration. Obviously, the purple colour corresponding to V element has a lower intensity than Ni due to that the V element is concentrated in the core part. In order to further confirm the distributions of various elements in the core and shell areas, EDS linear element scanning is performed. As shown in Figure 2.4 (g-h), more Ni elements in the nanosheet region (shell) than nanobelt part (core) are observed, revealing the formation of the CuVO_x core and NiO shell. Combining with the XRD analysis, it can be confirmed that the composite is consisted of CuVO_x nanobelt core and NiO nanosheet shell. Herein, as stated in the introduction section, the synergistic interaction between nickel and vanadium species should play a significant role in affecting the growth of such a special three-dimensional (3D) nano-flake

structure, which could provide high surface area, easily accessible active sites and shortened charge transfer route during the reaction [19]. In comparison, those surface morphologies of the prepared NiO-CuO@CP, NiO-VO_x@CP and V₂O₅@CP electrodes are presented in Figure 2.5. One can see that NiO-CuO@CP has a fluffy-like structure, which is different from that of CuVO_x-NiO@CP (Figure 2.4d). As shown in Figure 2.5c, the pure vanadium oxide (V₂O₅) grows along the carbon fiber with a denser layer microstructure, which should not be benefit for the electrocatalytic performance. However, as indicated in this study and other report [31], the coexistence of V and other metal species, the composite with 2D/3D structure could be more easily formed.

Figure 2.4 SEM images of (a-b) CuVO_x@CP, (c) NiO@CP, (d-f) CuVO_x-NiO@CP at different magnifications; (g-h) EDS line scan of Ni, Cu, O and V on CuVO_x-NiO@CP.

TEM analysis was carried out to investigate nanostructure of the synthesized electrocatalysts. When CuVO_x is synthesized on the CP, the interplanar spacing of 0.28 nm, which is assigned to the (003) plane of CuV₂O₅, is observed (Figure 2.6a). Herein, the edge dislocations, which should provide active sites for HER, are also observed. Meanwhile, on the TEM image of CuVO_x-NiO supported on the CP (Figures 2.6(b-c)), the lattice fringes of 0.24 and 0.27 nm are in good agreement with the (131) and (012) planes of Cu₂V₂O₇ and Cu₃V₂O₈, respectively. While, the lattice spacings of 0.15 and 0.20 nm correspond to the (220) and (200) planes of NiO. It is reported that both Cu₂V₂O₇ and Cu₃V₂O₈ have highly distorted structures with rich-defects [32]. As illustrated in Figure 2.6d, the edge dislocation resulted from the Burgers vectors could be generated in these materials, which always accompanies by lots of vacancies [33]. In addition, the typical TEM-EDS mappings exhibit the uniform distributions of Cu, V and Ni on the electrocatalyst (Figures 2.6 (e-h)).

Figure 2.6 TEM images of (a) CuVO_x; (b) CuVO_x-NiO composite on CP with lattice fringes of CuVO_x; (c) lattice fringes of NiO on CuVO_x-NiO@CP; (d) Schematic illustrations of edge dislocations; (e-h) the corresponding EDS elemental mappings of Cu, V and Ni.

Chemical composition and elemental valences of CuVO_x-NiO on CP were further investigated by XPS analysis (Figure 2.7). The atomic percentages of Ni, Cu, V and O elements based on XPS analysis are presented in Table 2.1, which reveal that more Ni species exist on the surface of the electrocatalyst since NiO is anchored on the CuVO_x surface. The peaks located at 856.1 and 873.9 eV with two satellite peaks (862.1 and 880.3 eV) on the XPS spectra of Ni 2p_{3/2} and Ni 2p_{1/2} indicate the presence of Ni²⁺ [34].

Table 2.1 Atomic composition of CuVO_x-NiO based on XPS analysis.

Electrocatalyst	% Atom			
	Ni	Cu	V	O
CuVO _x -NiO	31.8	6.82	2.75	58.63

The peaks located at 854.9 and 872.9 eV together with two peaks at 856.8 and 874.8 eV are indexed to the XPS spectra of Ni 2p_{3/2} and Ni 2p_{1/2}, respectively, which indicate the presence of Ni²⁺ and Ni³⁺ (Figure 2.7b). While, as shown in Figure 2.7c, the fitted peaks located at 935.2 and 955.3 eV relating to Cu²⁺ accompanying with the peaks at 933.6 and 953.4 eV relating to Cu⁺ on the XPS spectra of Cu 2p_{3/2} and Cu 2p_{1/2} are also observed, indicating the presence of mixed valences of Cu species. Herein, the splitting energy between Cu 2p_{3/2} and Cu 2p_{1/2} is 20.1 eV and three satellite peaks at 941.3, 943.8 and 962.6 eV are also found, which indicate that Cu species could be inserted into VO_x lattice [35]. In Figure 2.7d, two peaks of V 2p_{3/2} (516.9 eV) and V 2p_{1/2} (523.9 eV) are assigned to V⁴⁺ while the deconvolution of the V 2p_{3/2} peak located at 517.5 eV and the satellite peak of V 2p_{1/2} at 524.9 eV with the spin-orbital splitting energy of about 7.4 eV correspond to the V⁵⁺ oxidation state, which is well consistence with the XRD result [36]. For XPS spectrum of V 2p in V₂O₅@CP (Figure 2.8a), there are only two peaks of V 2p_{3/2} and V 2p_{1/2} at 517.3 and 524.3 eV, which correspond to V⁵⁺ of V₂O₅. It is reported that V⁴⁺ ion is always associated with the oxygen vacancy coupled with the V⁵⁺ ion [37]. As such, the presence of V⁴⁺ in both CuVO_x and CuVO_x-NiO should play a crucial role in the generation of the defect structure associated with the oxygen vacancy. In other words, the recrystallization of vanadium pentoxide (V₂O₅) in the presence of Cu²⁺ and Ni²⁺ ions should have enhanced the oxygen deficiency and defect sites [38]. Additionally, for O 1s XPS spectrum in CuVO_x-NiO, the main peak appeared at 530.2 eV could be assigned to the lattice O²⁻ ions (O_L). Besides, the binding energy gap between O 1s and V 2p of about 12.7 eV confirms the existence of V⁵⁺ species [23, 39]. The peak at high binding energies at about 531.7 and 532.7 eV are assigned to the defect sites with low oxygen coordination (O_V) and surface adsorbed water (O_C), respectively [27, 40]. In order to confirm the relative ratios of oxygen vacancies, the

O1s peak areas between CuVO_x and CuVO_x-NiO are compared in the Table 2.2. After NiO is composited with CuVO_x, the intensity of peak relating to oxygen vacancy is dramatically increased from 0.172 to 0.289, confirming that more O vacancies should be generated with the presence of NiO due to the structure reconstruction and recrystallization during the reaction [41]. Moreover, multivalent states of vanadium and rich-defect structure could either improve the electronic and ionic conductivities or accelerate the charge transfer kinetics for the electrochemical reactions [42]. Therefore, the co-existence of Cu²⁺, Cu⁺, V⁵⁺, V⁴⁺ and Ni²⁺ species in the CuVO_x-NiO electrocatalyst is expected to exhibit the superior performance for HER. These results also correspond to the HRTEM observation.

Figure 2.7 (a) Survey XPS spectrum; (b) Ni 2p XPS spectrum; (c) Cu 2p XPS spectrum; (d) V 2p XPS spectrum and (e) O 1s XPS spectrum of CuVO_x-NiO electrocatalyst.

Figure 2.8 XPS spectra of (a) V 2p and (b) O 1s of V_2O_5 , $CuVO_x$ and $CuVO_x-NiO$.

Table 2.2 The relative ratios of O1s peak areas based on XPS analysis

Electrode	Relative ratio of O1s peak areas		
	Lattice oxygen (O_L)	Oxygen vacancies (O_V)	Chemisorbed oxygen (O_C)
$V_2O_5@CP$	0.613	-	0.387
$CuVO_x @CP$	0.753	0.172	0.075
$CuVO_x-NiO@CP$	0.459	0.289	0.252
$CuVO_x-NiO@CP$ after HER	0.280	0.447	0.273

To further verify the composition of $CuVO_x-NiO$, Raman spectroscopy was also measured. As shown in Figure 2.9, the main peak of V-O stretching at 998 cm^{-1} in pure V_2O_5 (Figure 2.9a) shifts to 895 cm^{-1} in $CuVO_x$ (Figure 2.9b) and 820 cm^{-1} in $CuVO_x-NiO$ (Figure 2.9c), which should be attributed to the substitution of Cu and/or Ni in the lattice of V_2O_5 [43]. In addition, the Raman scatterings at 263 and 340 cm^{-1} (Figure 2.9c) correspond to Cu-O stretching whereas the peak at 538 cm^{-1} is ascribed to the vibration of Ni-O [23]. These results also indicate the successful formation of $CuVO_x-NiO$ electrocatalysts.

The contact angle was examined to understand the surface wettability and aerophobic properties of the catalyst surface for the HER [15]. As shown in Figure 2.10, the water contact angles (WCAs) of bare CP, V_2O_5 @CP, $CuVO_x$ @CP, NiO @CP and $CuVO_x$ - NiO @CP are 131.5°, 124.1°, 48.3°, 0° and 0°, respectively, indicating that the $CuVO_x$ - NiO @CP has super-hydrophilic property with a WCA of 0°. This super-hydrophilic surface of $CuVO_x$ - NiO @CP should be due to the good water adsorption ability of NiO nanosheet shell, which could promote the Volmer step of HER in alkaline electrolyte. Simultaneously, the generated hydrogen gas could be more easily detached from the electrode surface during the HER process [44]. The fast hydrogen desorption is also beneficial for keeping the nucleation sites free for new hydrogen generation, inducing more favorable contact points around the catalytic active sites, thereby leading to sufficient contact between the electrode and electrolyte [45, 46].

2.3.2 Catalytic HER performance and stability

HER performances of all fabricated electrodes were evaluated in 1 M KOH solution with a scan rate of 1 mVs^{-1} in the three-electrode system. As shown in Figure 2.11a, the $CuVO_x-NiO$ @CP electrode exhibits an overpotential of $74 \text{ mV}@10 \text{ mAcm}^{-2}$, which is lower than those of $NiO-CuO$ @CP ($83 \text{ mV}@10 \text{ mAcm}^{-2}$) and $CuVO_x$ @CP ($124 \text{ mV}@10 \text{ mAcm}^{-2}$). The overpotential of $CuVO_x-NiO$ @CP catalyst is not only comparable to that of Pt/C but also lower than those recently reported data on the similar materials (Table 2.3).

Meanwhile, from Figure 2.11b, Tafel slopes relating to the $NiO-CuO$ @CP, $NiO-V_2O_5$ @CP, $CuVO_x$ @CP, V_2O_5 @CP and $CuVO_x-NiO$ @CP electrodes are 75.8, 158.4, 132.5, 163.6 and 60.8 mV dec^{-1} , respectively. Herein, the $CuVO_x-NiO$ @CP electrode also exhibits the lowest Tafel slope, implying that the fastest kinetics occur on this electrode. Based on the Tafel slope value (60.8 mV dec^{-1}) of $CuVO_x-NiO$ @CP electrode, the HER over it should obey the Volmer-Heyrovsky mechanism. As stated above, the NiO shell is benefit for the H_2O adsorption and decomposition with the reduced energy barrier at the initial water dissociation step followed by a H_2 desorption step. It is reported that the NiO (111) site could accelerate water dissociation step due to the strong adsorption ability and high surface wettability, where H_2O molecule can be easily dissociated into intermediate H_{ads} and OH^- (Volmer step ; $H_2O + e^- \rightarrow H_{ads} + OH^-$) [16, [47-49]]. Then, the produced H_{ads} could be easily to absorb on the O

vacancies sites of $\text{VO}_x\text{-Cu}_2\text{O/Cu}$ (the real active species), and subsequently combine with another H_{ads} from the water dissociation with a hydrogen desorption step (Heyrovsky step; $\text{H}_2\text{O} + \text{e}^- + \text{H}_{\text{ads}} \rightarrow \text{H}_2 + \text{OH}^-$). Therefore, the oxygen vacancy defects could promote the Heyrovsky step of HER in alkaline solution by facilitating the conversion of adsorbed H intermediate to H_2 , and enhance electrical conductivity due to the electron hopping between different valence states of metal-O sites [26]. Thus, the synergistic effect of the NiO and CuVO_x could promote water dissociation, especially hydrogen desorption step, thereby improving the HER activity.

Figure 2.11 Electrocatalytic performances of the prepared electrodes in 1 M KOH solution. (a) LSV curves; (b) Corresponding Tafel plots; (c) EIS Nyquist plots; (d) Overpotentials at two different current densities of 10 and 50 mA cm^{-2} .

According to Butler-Volmer equation with microkinetic analysis, the Tafel slope value is in the range of 40-120 mV dec^{-1} , indicating that the amount of active sites does not limit the reaction rate while the Heyrovsky step could be determined as the rate

determined step [50, 51]. Figure 2.11c shows EIS analysis results, in which the spectrum at the high frequency stands for the internal resistance of electrode (R_s) while the semicircle radius indicates the charge-transfer resistance (R_{ct}). One can see that the R_s values of NiO-CuO@CP, NiO-V₂O₅@CP, CuVO_x@CP, V₂O₅@CP and CuVO_x-NiO@CP are 3.73, 3.20, 1.23, 1.68 and 1.55 Ω/cm^2 with the corresponding R_{ct} values of 2.09, 13.80, 2.11, 33.07 and 0.72 Ω/cm^2 , respectively. It indicates that the CuVO_x-NiO@CP electrode has the lowest resistance for the charge transfer, which is also agreement with its electrocatalytic performance. These results confirm that the CuVO_x binary metal oxides combined with the NiO lamellar nanosheets can effectively enhance the charge transfer properties. The synergetic coupling of the CuVO_x with high conductivity and NiO lamellar nanosheets with a high surface area could provide effective electron transportation and sufficient contact area between the electrode and electrolyte, thereby resulting in the improved HER performance [43, 52]. In addition, the CuVO_x-NiO@CP electrode also shows an overpotential as low as 148 mV for the generation of a higher current density of 50 mA/cm² (Figure 2.11d), suggesting that it has the potential for the practical application.

Cyclic voltammetry (CV) at the non-faradic potential range was conducted in order to measure the electrochemical active surface area (ECSA) of all prepared electrodes (Figure 2.12). Figure 2.13a shows the electrochemical active surface areas (ECSAs) of different synthesized electrodes and Table 2.4 summarizes the related other parameters. The normalized ECSA was calculated by setting the ECSA of carbon paper as 1. As such, the normalized ECSA of NiO-CuO@CP, CuVO_x@CP and CuVO_x-NiO@CP are 86.2, 74.4 and 182, respectively, indicating that synergistic interaction between nickel and vanadium species should play a crucial role for improving the ECSA due to the formation of lamellar NiO nanosheets on the CuVO_x layer. Obviously, the CuVO_x-

NiO@CP electrode displays 2.1 and 2.4 times higher ECSAs than those of NiO-CuO@CP and CuVO_x@CP electrodes, respectively, proving that this electrode has enriched active sites and high surface roughness. Moreover, the excellent intrinsic activity of CuVO_x-NiO@CP is further confirmed by ECSA-normalized current density. As shown in Figure 2.14, CuVO_x-NiO@CP obviously exhibits a higher electrocatalytic activity than others electrode, further implying its high intrinsic activity [65, 66].

Table 2.3 Comparison of HER activity of CuVO_x-NiO electrocatalysts with the recently reported data

Electrocatalysts	Electrolyte	Overpotential at 10 mA cm ⁻² (mV)	Reference
CuVO _x -NiO@CP	1M KOH	74	This work

Figure 2.13b shows multi-step chronopotentiometry measured from 10 to 300 mA cm⁻² with a 50 mA cm⁻² increment every 500 s and then going back to 10 mA cm⁻² after 300 mA cm⁻² operation for the CuVO_x-NiO@CP electrode. One can see that this electrode maintains the potentials at different constant current densities with excellent

recyclability due to its good electro-conductivity, superb mass transport property and mechanical robustness for HER in the alkaline solution. Moreover, as can be seen in Figure 2.13c, the LSV curve after 1000-cycle testing has no apparent change in the HER activity. Meanwhile, for the chronopotentiometry measurement at a constant current density of 10 mA cm^{-2} in 30 h, the potential to achieve the standard 10 mA cm^{-2} current density remains constant when the testing is performed in a continuous flowing 1 M KOH solution (Figure 2.13d).

Figure 2.14 HER performance normalized by ECSA.

Post-characterization of CuVO_x-NiO@CP further supports the excellent stability of catalyst. As displayed in Figure 2.15a, the morphology of CuVO_x-NiO@CP after the stability testing maintains almost unchanged, especially the lamellar nanosheet layer is obviously observed. Herein, one can see that some tiny spherical particles appear in the space among the nanosheets, suggesting that some new phases should be formed during the HER process, which is also confirmed by the EDX elemental mapping (Figure 2.16). TEM image of the electrocatalysts after the HER is presented in Figure 2.17. Herein, the lattice spacing of 0.20 nm corresponding to the (200) plane of NiO is retained. Meanwhile, the lattice fringes assigned to (111) and (200) planes of Cu₂O and Cu are also observed, suggesting that the recrystallization of CuVO_x occurred during the HER process. Moreover, XRD pattern of the spent CuVO_x-NiO@CP after the stability test is displayed in Figure 2.15b, in which the diffraction peaks located at 2θ of 43.4°, 50.6° and 74.2° relating to (111), (200) and (220) planes of Cu (JCPDS No. 04-0836) and the characteristics peaks at 36.5°, 42.4°, 61.5° and 73.7° corresponding to (111), (200), (220) and (311) planes of Cu₂O (JCPDS No 75-1531) are also found. The peaks of

Cu_2O and Cu should be generated from partial reduction of Cu species in CuVO_x in alkaline solution, confirming by XRD peak of CuVO_x/CP after HER [67]. Meanwhile, the diffraction peaks of NiO are remained.

Figure 2.15 (a) SEM image and (b) XRD pattern of $\text{CuVO}_x\text{-NiO@CP}$ after long-term stability test.

Figure 2.16 SEM images of (a) $\text{CuVO}_x\text{-NiO@CP}$; and (b-e) the corresponding EDX mappings of Cu, O, Ni and V after the stability test.

Figure 2.17 TEM image of CuVO_x-NiO@CP after the stability test.

This phenomenon is further analyzed by XPS analysis. As displayed in Figure 2.18a, the peaks located at 954.4 and 934.9 eV relating to Cu 2p_{1/2} and Cu 2p_{3/2} of Cu²⁺ still exist but the peak intensities of Cu 2p_{1/2} and Cu 2p_{3/2} after the stability test are increased sharply and shifted toward the lower binding energy, suggesting the transformation of CuO to Cu₂O (Cu⁺) or metallic copper (Cu⁰) at 932.9 and 952.8 eV because Cu (II) species can be reduced to Cu₂O (I) and Cu (0) driven by electron in the redox reaction [68]. However, it should be noted that it is difficult to distinguish the Cu₂O and metallic Cu with the XPS analysis results owing to the similar binding energies of Cu 2p_{3/2} and Cu 2p_{1/2} for the Cu₂O and Cu 2p for the Cu(0). Notably, the presences of both stable Cu₂O/Cu and/or Cu₂O/CuO composites could enhance the catalytic activity, leading to the good stability in alkaline solution [57, 69]. Onsten *et. al.* [70] reported that H from water prefers to be adsorbed at uncoordinated oxygen sites/defects of Cu₂O (111), and oxygen species in water can interact with the surface copper species, resulting in a weaker O-H bond, which can accelerate water dissociation. Hence, the presence of a small amount of Cu(I)/Cu(0) species with an oxophilic surface of NiO-CuVO_x could promote water dissociation by lowering the energy barrier and enhancing the

recombination reaction of H_{ads} to H_2 at the metal surface, resulting in increased HER activity in alkaline condition [71, 72].

Figure 2.18 (a) Cu 2p XPS spectrum, (b) V 2p XPS spectrum, (c) O 1s XPS spectrum and (d) Ni 2p XPS spectrum of CuVO_x-NiO after the long-term stability test for 30 h.

Besides, the presence of metallic Cu(0) could enhance intrinsic conductivity of the electrode. As can be seen in Figure 2.18b, the peaks of V 2p spectra are slightly decreased, which can be attributed to the partial dissolution of VO_x caused by the weak bonding between VO_x and Ni species. However, the valence states of V⁵⁺ and V⁴⁺ at 517.3 and 518.3 eV are almost remained [3]. On the O 1s spectrum, three peaks at 530.8, 532.1 and 533.1 eV correspond to the lattice oxygen (O_L), the native defects of O²⁻ vacancies (O_V) and the chemisorbed oxygen closely related to -OH groups on the surfaces of metal oxides (O_C), respectively (Figure 2.18c) [71]. The intensities of peaks relating to the metal oxide on the surface are decreased while those corresponding to the oxygen vacancies and surface absorbed oxygens/hydroxide are increased,

confirming the transformation of CuO to Cu₂O/Cu species with the loss of oxygen atoms after recrystallization during the HER process. In addition, the relative ratios of O 1s peak areas are summarized in the Table 2.5. Notably, the fraction of oxygen vacancies is increased from 0.289 to 0.447 after the long-term operation, which might be caused by the weakening of M-O bonds. Herein, the generation of O vacancies could promote the Heyrovsky step since the O vacancies can promote H_{ads} adsorption kinetics as well as the desorption of H₂. Meanwhile, Ni 2p XPS spectrum maintains unchanged, implying that the valence states of Ni²⁺ and Ni³⁺ maintain stable in the alkaline condition (Figure 2.18d). Moreover, the relative Cu content is increased from 6.82% to 8.64%, also confirming the generation of Cu₂O and Cu species during the HER in alkaline solution. These post characterizations prove that the VO_x-Cu₂O/Cu and NiO species should act as the real active species for the HER. In addition, it should be noted that the response current density of HER does not decrease during the conversion of Cu based species according to the long-term stability test, which might be due to that the reaction current of CuVO_x conversion is not obvious and the formed Cu₂O/Cu and VO_x are the stable forms. Here, the robust stability still observed after a long-term operation should rely on the recrystallization on the Cu species sites from CuVO_x-NiO to the stable VO_x-Cu₂O/Cu-NiO. As such, the presence of mixed valence states of Cu species and stable morphology from the strong interaction between CuVO_x and NiO nanosheets with high surface roughness could provide an outstanding intrinsic activity with strong adsorption of electroactive species, which are beneficial for the HER [73, 74]. In addition, the hydrogen production during a certain period of water electrolysis was also investigated. As shown in Figure 2.19, the Faradaic efficiency of CuVO_x-NiO@CP electrode reaches 97%. Therefore, the CuVO_x-NiO@CP electrode can provide fast

charge transfer rate, quick hydrogen bubble releasing, thereby exhibiting good robustness and durability under HER in the alkaline electrolyte.

Table 2.5 The relative ratios of O1s peak areas based on XPS analysis

Electrodes	Relative ratio of O1s peak areas		
	Lattice oxygen (O _L)	Oxygen vacancies (O _V)	Chemisorbed oxygen (O _C)
V ₂ O ₅ @CP	0.613	-	0.387
CuVO _x @CP	0.753	0.172	0.075
CuVO _x -NiO@CP	0.459	0.289	0.252
CuVO _x -NiO@CP after HER	0.280	0.447	0.273

Figure 2.19 Theoretical hydrogen evolution amount compared with the measured hydrogen evolution amount for HER over the CuVO_x-NiO@CP electrode.

2.4 Conclusions

By utilizing a simple hydrothermal process with a calcination step, an O vacancy-rich CuVO_x nanobelt@NiO nanosheet composite was successfully coated on the carbon paper. Especially, the generation of real active species VO_x-Cu₂O and Cu-NiO during the HER could further increase the intrinsic activity with the maintained morphology. The composite had excellent electrocatalytic HER performance in the alkaline solution with an overpotential as low as 74 mV at 10 mA cm⁻² and a fast kinetic reaction with a small Tafel slope of 60.8 mVdec⁻¹, as well as excellent stability and recyclability, significantly better than those reported similar bi-metal oxide based electrocatalysts. The outstanding catalytic performance could be attributed to the effective adsorption and decomposition of H₂O to H_{ads} intermediate by synergistic effect between hydrophilic surface of NiO and the O vacancy-rich CuVO_x, allowing the generated H_{ads} on the NiO to be easily adsorbed on the O vacancy of VO_x-Cu₂O, thereby converting to H₂. This innovative design could be useful in the development of low-cost electrocatalysts for the application in alkaline electrolyzers.

CHAPTER 3 Highly durable FeNiS_x/NiFe(OH)_x

electrocatalyst for selective oxygen evolution reaction in

alkaline simulated seawater at high current densities

3.1 Introduction

Hydrogen production via water electrolysis by using electricity produced from waste heat or renewable energy without CO₂ emission is a clean and secure technology [1]. However, fresh water is a limited resource while the seawater is an abundant one [2]. Water electrolysis consists of two main reactions, i.e., Hydrogen Evolution Reaction (HER) and Oxygen Evolution Reaction (OER). The sluggish OER at the anode generally requires a large overpotential to overcome the energy barrier and energy loss since it involves multiple steps to cleavage water molecule (H₂O) with a 4-electron pathway so that the electrocatalysts with high performance are highly required [3]. For seawater electrolysis, two 2-electron reactions, i.e., chlorine evolution reaction (ClER, $2\text{Cl}^- \rightarrow \text{Cl}_2 + 2\text{e}^-$) and hypochlorite generation reaction (HGR, $\text{Cl}^- + 2\text{OH}^- \rightarrow \text{ClO}^- + \text{H}_2\text{O} + 2\text{e}^-$), could competitively occur on the anode with the OER in the acidic and alkaline conditions, respectively, especially at a high current density, owing to the presence of large amount of chloride ions (~0.5 M) and kinetic advantage of them although OER is thermodynamically favored over either ClER or HGR [4-6]. In general, in the alkaline solution (pH > 7.5), if those obtained electrocatalysts can be operated at an overpotential lower than 480 mV, HGR will not occur to compete with OER. In addition, the chlorine in seawater could result in electrode erosion and electrode degradation [7]. Therefore, the electrocatalysts for seawater electrolysis should have an overpotential lower than 480 mV to avoid the hypochlorite formation and corrosion in the alkaline condition [8]. Besides, to meet the practical industrial-scale requirements,

the electrocatalysts should be operated at a current density as high as $1 \text{ A} \cdot \text{cm}^{-2}$ or more to achieve a high hydrogen production rate under long-term operation [9, 10]. Unfortunately, to date, only a few works on OER catalysts have been explored at such highly-harsh conditions and most of the developed catalysts are always deactivated during the OER process, particularly at a high current density. For example, Zhou *et al.* [11] measured the stability of NiFe-LDH on Cu nanowires but this catalyst is not stable at a high current density (500 mA cm^{-2}) under alkaline solution (1 M KOH). Gupta *et al.* [12] investigated OER in saline water (1 M KOH + 0.5 M NaCl) using a bimetallic oxy-boride (Co-Fe-O-B) catalyst, which exhibited a low overpotential of 294 mV at 10 mA cm^{-2} , but the current lost nearly 35% after 20 hours of operation. While, the faradaic efficiency at a high current density (100 mA cm^{-2}) was also decreased from nearly 100% to ~74% due to Cl^- oxidation. Herein, it is considered that the lower stability and performance was attributed to the presence of corrosive Cl^- ions in the solution.

Among various OER electrocatalysts, Ni-Fe oxides, hydroxides, (oxy)hydroxide and their layered double hydroxides have been reported to be a class of electrocatalysts with excellent OER activity even in alkaline electrolytes [7, 13]. However, these electrocatalysts always have low conductivity, less active sites, insufficient intrinsic activity and poor stability especially in saline water at a high current density [14, 15]. To solve these issues, phosphorization, boronation, sulfidation and nitridation of them and incorporation them with other materials could tune the intrinsic activity [16]. For instance, Zou *et al.* [17] combined NiFe-LDH and NiFeS_x as the electrocatalyst, which exhibited a low overpotential of 210 mV at 10 mA cm^{-2} for OER since the chemisorption free energy of O^* ($E(\text{O}^*)$) of NiFe-LDH can be reduced from 0.90 to 0.53 eV by the combination of it with NiFeS_x . Herein, the charge redistribution on the interface of the two materials contributed to the improvement of OER activity through

the enhancement of affinity to the O* intermediates and the improvement of electrical conductivity by the incorporated metallic NiFeS_x species. Yuan *et al.* [18] reported that sulfur doping can increase the OER activity of FeCoOOH with a lowered catalytic overpotential (225.3 mV at 20 mA cm⁻²). By density functional theory (DFT) calculations, it is revealed that a synergistic effect between two coordinating S and one adjacent Fe can optimize the electronic state of Co, resulting in the decreasing in binding energy of OH* (ΔE_{OH}) and tuning of the electronic structure. Shuang *et al.* [14] prepared NiFe(OH)_x electrocatalyst with abundant oxygen vacancy-rich amorphous structure on the carbon paper (CP), which demonstrated a low overpotential of 303 mV at 100 mA cm⁻² and high durability without the degradation for 50 h. Such a superior performance could be attributed to the synergistic effect between Ni and Fe species. Recently, Zhang *et al.* [19] doped S into FeOOH/IF to lower the energy barrier of rate determining step in OER, thereby improving the electrocatalytic performance. Liu *et al.* [20] embedded Ag on the NiFe-LDH, which exhibited superior activity by requiring a low overpotential of 303 mV at 1,000 mA cm⁻² in 1 M KOH seawater solution. DFT calculations showed that the Ag doping improved the phase stability of NiFe-LDH with triggering lattice oxygen, implying high mechanical robustness. Yu *et al.* [21] successfully synthesized S-doped Ni/Fe(oxy)hydroxide, which displayed excellent OER performance in the seawater electrolyte with a low overpotential of 278 mV at 100 mA cm⁻². The excellent catalytic performance could be attributed to hydrophilic property, highly porous nanostructure and good corrosion resistance from metal(oxy)hydroxide. Dionigi *et al.* [6] also studied the NiFe-LDH for selective seawater electrolysis, achieving overpotentials of 360 and 359 mV at 10 mA cm⁻² in alkaline freshwater and saline electrolytes, respectively. For scaling up from lab scale to industrial level using natural seawater as a water resource, it requires consideration

of either electrocatalytic performance or the catalyst preparation step as well as the cost of chemical substances need to be considered. Thus, searching for preparation of earth-abundant and cost-effective electrocatalysts with high durability, especially at a large current density for overall seawater electrolysis using a facile strategy is still full of challenges but necessary.

In this study, *in-situ* growing of $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ composite with a two-dimensional (2D) nanosheet structure on nickel foam (NF) is simply realized using a corrosion engineering process followed by a fast and mild sulfurization step in order to reduce catalyst preparation cost and time and simultaneously decrease interfacial resistance between the electrocatalyst and the substrate, increase electrical conductivity, and prevent electrocatalyst peeling off from the substrate during the long-term operation at a high current density. The evaluation of electrocatalytic performances is performed in the alkaline freshwater solution at first, and then a simulated seawater is used to confirm its suitability as a bifunctional electrocatalyst, especially as a selective OER electrocatalyst for the seawater electrolysis. It is found that the obtained $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ composite based electrode has excellent electrocatalytic activity with a low overpotential of 270 mV for the OER in alkaline simulated seawater at 100 mA cm^{-2} and it can even work stably over 100 h at a current density as high as 1 A cm^{-2} . For the overall seawater electrolysis using a two-electrode system, it is capable to sustain stable up to 1 A/cm^2 in the imitate seawater solution with a cell voltage of 2.81 V, achieving a high hydrogen productivity without the catalyst deterioration while the faradaic efficiencies of hydrogen and oxygen production are as high as 95% and 94% in the electrolysis of alkaline simulated seawater, respectively.

3.2 Experimental section

3.2.1 Chemical and Materials

Iron (III) chloride hexahydrate ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$), sodium nitrate (NaNO_3 , 99%), urea ($\text{CH}_4\text{N}_2\text{O}$), sodium sulfide (Na_2S , 98%), sodium chloride (NaCl , 99%), hydrochloric acid (HCl , 69%), potassium hydroxide (KOH , 85%) and ethanol ($\text{C}_2\text{H}_5\text{OH}$, 99.5%) were purchased from Wako, Japan. deionized (DI) water ($<18.2 \text{ M}\Omega \text{ cm}$) was used to prepare the solution. Nickel foam (NF, 1.5 mm of thickness, 0.23 g/cm^3 bulk density and 110 pores/inch) was purchased from MTI, Japan.

3.2.2 Synthesis of $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x/\text{NF}$ electrode

Before fabrication of $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x/\text{NF}$ electrode, NF substrate ($2 \times 2 \text{ cm}^2$) was treated in 1 M HCl solution for 1 hour under sonication, and then washed with ethanol and DI water consecutively for 1 h in each step followed by drying for 1 hour in a vacuum oven at 60°C to remove the oxide layer and other impurities. Thereafter, the treated NF was immersed into 50 ml of aqueous solution containing 0.5 mmol of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ and 2.5 mmol of NaNO_3 to perform the reaction at 100°C for 2 h. Then, the electrode was washed with distilled water and ethanol successively for 3 times and dried in vacuum oven at 60°C for 12 h. As such, the obtained dark-yellow electrode is called $\text{NiFe}(\text{OH})_x/\text{NF}$. Thereafter, the $\text{NiFe}(\text{OH})_x/\text{NF}$ electrode was mildly sulfurized by using 1 g of Na_2S with 10 mmol of $\text{CH}_4\text{N}_2\text{O}$ in aqueous solution at 25°C for 1 h and then, dried in vacuum oven at 60°C for 12 h. As such, the $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ with a nanosheet structure in black color was uniformly coated on the NF skeleton. Herein, the loading amount of $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ was estimated to be ca. 0.30 mg cm^{-2} by weighing the electrode before and after the synthesis. For comparison, $\text{Ni}_x\text{S}_y/\text{NF}$ electrode was also prepared using the similar method but not using Fe species in the initial stage.

3.2.3 Material Characterizations

Morphology and nanostructure of the electrocatalyst were determined by a scanning electron microscope (SEM, SU8010, Hitachi, Japan) and a transmission electron microscope (TEM, JEM-2100F, JEOL, Japan). Chemical valences and composition of the prepared electrocatalysts were characterized by XPS measurement using a VG Scientific ESCALab250i-XL instrument with an Al-K α X-ray source and crystalline structure was analyzed by X-ray diffraction (XRD) measurement in a 2θ range of 10° - 80° with a Rigaku Smartlab diffractometer (Japan) using a Cu-K α as the radiation source ($\lambda=0.15406$ nm). Raman spectrum was recorded using a JASCO NRS-5100 ($\lambda=532$ nm).

3.2.4 Electrochemical measurements

Performances of all prepared electrodes were examined using a three-electrode system on an electrochemical workstation (Versa STAT4, Princeton, USA). A standard Hg/HgO electrode was used as the reference electrode, a carbon rod was used as the counter electrode and the as-prepared catalysts were used directly as the working electrode. A linear sweep voltammetry (LSV) with a scan rate of 2 mV s^{-1} in a potential range of 0.176-1.076 V was used to evaluate the OER performance. Two different electrolytes including alkaline freshwater solution (1 M KOH) and alkaline-simulated seawater solution (1 M KOH + 0.5 M NaCl) were used in the experiment (pH \sim 14)[4]. The potential with respect to reversible hydrogen electrode (RHE) was calculated by the Nernst equation: $E(\text{vs RHE}) = E(\text{Hg/HgO}) + 0.098 + 0.059 \text{ pH}$. The corresponding overpotential (η) for OER can also be calculated using the formula; $\eta = E(\text{RHE}) - 1.23 \text{ V}$. Electrochemical impedance spectroscopy (EIS) measurement was performed at a frequency range of 100 kHz-0.1 Hz. The potential range of cyclic voltammetry (CV) measurement at a scan rate range of $10\text{-}100 \text{ mV s}^{-1}$ was - 0.2-0 V (vs. RHE), which was

applied to evaluate the electrochemical active surface area (ECSA). The OER durability test was performed for 100 hours at room temperature with constant current densities of 100 and 1,000 mA cm⁻² in alkaline freshwater solution and alkaline simulated sea water solution, as well as accelerate degradation test (ADT) for 2000 cycles at a potential range from 0.1 to -0.3 V (vs RHE), respectively. In addition, overall seawater electrolysis was tested using a two-electrode system with the FeNiS_x/NiFe(OH)_x/NF electrode for both anode and cathode, where the polarization curve was measured in a potential range of 1.0-2.2 V at a scan rate of 2 mVs⁻¹ without iR-compensation and long-term durability was conducted using chronopotentiometry at 10, 100, 500 and 1,000 mA cm⁻² for 12 hours in alkaline freshwater solution (1 M KOH) and alkaline-simulated seawater solution (1 M KOH + 0.5 M NaCl).

3.2.5 DFT calculation

The spin-polarized DFT calculations were performed using the Vienna Ab-initio Simulation Package (VASP) [22]. Exchange-correlation functional was expressed using the generalization gradient approximation of Perdew, Burke and Ernzerhof (PBE) functional [23]. The U-J terms of Ni and Fe were set as 3.8 and 4.0 eV, respectively [24]. The plane wave energy cut-offs were set at 450 eV. A Monkhorst-Pack grid was used and the k-point mesh was thoroughly tested for structure relaxation and energy calculation. The Ni/Fe ratio of NiFe(OH)_x was considered to be 3:1 in construction of the models. The (001) facet was used as the calculation models for NiFe(OH)₂ and NiFeS(OH)₂. A vacuum region of 15 Å was applied to avoid interactions between two images along c axis and the layer space of 7 Å was set based on the experimental experience [25]. Residual forces were within 0.02 eV/Å for geometry optimizations. The adsorption energy relating to Cl atom is defined as follows;

$$E_{abs}=E_{tot}-E_{slab}-E_{cl-atom}, \quad \text{Eq. (1)}$$

where E_{tot} , E_{slab} and $E_{cl-atom}$ are the total energy of adsorbed system, the energy of clear surface and the energy of isolated Cl atom in a large cell, respectively.

3.3 Results and discussion

3.3.1 Characterization of FeNiS_x/NiFe(OH)_x/NF electrode

As indicated in the experimental section, the NiFe(OH)_x/NF electrode was prepared by submerging of the NF substrate in a solution containing oxidants including Fe³⁺, NO₃⁻ and dissolved oxygen at 100°C for 2 hours, in which the surface of NF can be oxidized spontaneously to NiFe(OH)_x. This is an oxidation effect of NaNO₃, which can change the near-surface chemical environment and allow more active sites to be formed on the NF surface. In this study, the NF was used as both nickel source and substrate. The effect of corrosion reaction time on the preparation of NiFe(OH)_x was also studied. As displayed in Figure 3.1, NiFe(OH)_x with a nanosheet structure was grown uniformly after 120-min corrosion reaction. Moreover, as shown in Figure 3.2, the optimal condition was chosen based on the lowest overpotential and charge transfer resistance. The results shows that NiFe(OH)_x performs best when synthesized at 100°C for 2 hours.

Figure 3.1 SEM images of (a) NiFe(OH)_x-30 min, (b) NiFe(OH)_x-60 min, (c) NiFe(OH)_x-120 min and (d) NiFe(OH)_x-180 min.

To generate FeNiS_x/NiFe(OH)_x on the NF, the obtained NiFe(OH)_x/NF electrode was further submerged in a 0.1 M Na₂S solution for anion-exchange. As shown in Figure 3.3a, in order to form the NiFe(OH)_x on the NF, the NO₃⁻ ions are reduced to hydroxide ions on the NF surface with the aid of electrons and subsequently interacted with Ni²⁺ from the dissolution of NF substrate. Then, in the presence of Fe³⁺ ions from FeCl₃ precursor, bimetallic hydroxide, i.e., NiFe(OH)_x, could be formed on the NF surface as indicated in the following equations: [26-28]

After the mild sulfurization with Na₂S, the color of obtained electrode is changed from dark-yellow to black, indicating that the FeNiS_x/NiFe(OH)_x/NF is obtained (Figure 3.3a).

Figure 3.2 LSV polarization curves; (b) corresponding Tafel slopes; (c) Nyquist plots NiFe(OH)_x/NF for OER in alkaline freshwater with 1.0 M KOH (corrosion time: 30, 60, 120 and 180 min are); and (d) overpotentials at 10 and 100 mA cm⁻² of all prepared electrodes.

As shown in Figures 3.3(b-c), NiFe(OH)_x nanosheets uniformly grow on the surface of NF without the addition of additional nickel source, ensuring robust physical contact of active catalyst layer to the substrate. After the mild sulfurization by anion-exchange reaction between S²⁻ (from Na₂S) and OH⁻ of NiFe(OH)_x, the original morphology is maintained (Figure 3.3c). Herein, since the solubility constant (K_{sp}) of sulfide is lower than that of hydroxide, the S²⁻ could partially substitute the OH⁻ to form FeNiS_x on the surface of NiFe(OH)_x. From the EDS elemental mapping (Figures 3.3(d-e)), one can see that Ni, Fe, O and S exist on the NF substrate and all these elements are homogeneously distributed. However, due to the high intensity peak of the nickel foam

substrate, no diffraction peaks corresponding to both metal hydroxides and metal sulfides are observed in the XRD patterns of the obtained NiFe(OH)_x and $\text{FeNiS}_x/\text{NiFe(OH)}_x$ (Figure 3.4). However, from the TEM images as shown in Figures 3.5(a-c), it can be found that FeS , Ni(OH)_2 and Fe(OH)_3 exist in the electrocatalysts with lattice spacings of 0.28 (111), 0.26 (101) and 0.27 (102) nm, respectively. More interestingly, lattice distortion is observed, implying that the sulfurization allows S atoms incorporating into the NiFe(OH)_x structure, which could improve the intrinsic activity of the obtained electrocatalysts. The corresponding nano-scale elemental mappings as shown in Figures 3.5(d-g) also confirm the uniform distribution of Ni, Fe, S and O elements on the nanosheets. The obtained $\text{FeNiS}_x/\text{NiFe(OH)}_x$ electrocatalyst was further characterized by Raman analysis. As shown in Figure 3.6a, the representative bands at around 470 and 540 cm^{-1} correspond to $\text{Fe}^{3+}\text{-Ni}^{2+}\text{-O-Ni}^{2+}$ and $\text{Fe}^{3+}\text{-O-Fe}^{3+}$ bonds in NiFe(OH)_x , respectively. While, the Raman center-band at 685 cm^{-1} could be attributed to the $\text{Fe}^{3+}\text{-O}$ vibration in the disordered Fe-OH clusters [29]. The broad peak with low intensity at 475 cm^{-1} also confirms the amorphous nature of NiFe(OH)_x [30]. After the sulfurization, the peaks at 330 and 355 cm^{-1} corresponding to the mackinawite FeS are observed, indicating that the S atoms has been doped into NiFe(OH)_x structure successfully [31].

Figure 3.3 (a) Schematic illustration of the FeNiS_x/NiFe(OH)_x/NF electrode fabrication procedure; (b) SEM images of the pre-treated NF; (c) surface of NiFe(OH)_x/NF electrode; (d) surface of FeNiS_x/NiFe(OH)_x/NF electrode; and (e) EDS elemental mappings of FeNiS_x/NiFe(OH)_x/NF electrode.

Figure 3.4 XRD patterns of as-prepared catalysts.

Figure 3.5 TEM images of (a) $\text{FeNiS}_x/\text{NiFe(OH)}_x$; (b,c) HR-TEM images and (d-g) corresponding EDS elemental mappings of Ni, Fe, S and O on $\text{FeNiS}_x/\text{NiFe(OH)}_x$ surface

Figure 3.6b displays XPS survey spectrum of the obtained $\text{FeNiS}_x/\text{NiFe(OH)}_x$, which further demonstrates the presence of Ni, Fe, O and S elements in this electrocatalyst. The high-resolution Ni $2p$ spectrum in Figure 3.6c shows two peaks at the binding energies of 855.9 and 857.1 eV, which correspond to Ni^{2+} and Ni^{3+} species, confirming the presence of Ni^{2+} and Ni^{3+} in $\text{FeNiS}_x/\text{NiFe(OH)}_x$. After the sulfurization, the peak

intensity corresponding to Ni^{2+} is increased when compared to that of $\text{NiFe}(\text{OH})_x$. Furthermore, compared with $\text{NiFe}(\text{OH})_x$ (Ni^{2+} : 856.3 eV), the Ni^{2+} peak position of $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ (Ni^{2+} : 855.9 eV) shifts to the lower binding energy direction since the electronegativity of S (2.58) is lower than that of O atom (3.44). It also indicates that incorporating S into $\text{NiFe}(\text{OH})_x$ crystal lattice via O site substitution can effectively improve electrocatalytic activity by creating more adsorption sites with high electron density and asymmetric charge density distribution, lowering OER overpotential [32]. As can be seen in Figure 3.6d, Fe $2p_{3/2}$ and Fe $2p_{1/2}$ of Fe^{2+} species are ascribed to the two peaks at 711.7 and 721.5 eV, respectively, whereas those of Fe^{3+} species are assigned to the coexistence peaks at 714.0 and 726.2 eV, respectively. Furthermore, after the sulfurization, the corresponding peak intensity of Fe^0 metal species at 707.0 eV is increased while the Fe $2p$ spectrum shifts about 0.30 eV higher than that in the $\text{NiFe}(\text{OH})_x$, implying that the incorporating of S atoms can enhance the coordination ability of Fe and formation of FeS ($\text{Fe}^{2+} + \text{S}^{2-} \rightarrow \text{FeS}$) species on the surface of $\text{NiFe}(\text{OH})_x$, which could considerably improve the conductivity, thereby benefiting for OER. The O $1s$ peak can be decomposed into three peaks at 530.7, 531.4 and 532.1 eV, corresponding to O^{2-} , OH and surface absorbed water/oxygen defect sites, respectively (Figure 3.6e) [33]. On the high-resolution S $2p$ spectrum, the peaks at 162.1 and 163.3 eV correspond to S^{2-} (S-S) and S_2^{2-} (S-M) in FeNiS_x , respectively (Figure 3.6f). Moreover, the peak at 168.6 eV should be attributed to surface oxidation with the formation of S-O bond relating to the sulfurization. As can be seen from Figure 3.6c, after the sulfurization, the binding energy of Ni is shifted negatively because the sulphur (S) has a lower electronegativity with higher polarization degree so that it is easier to be polarized and shares more electrons with the foreign metal in order to balance the strong positive field of Ni. Herein, the lowering of binding energy could make Ni

receive more electrons from the S after the sulfurization step. Meanwhile, in the O *1s* spectrum, the binding energy also shifts negatively, which should be attributed to the partial substitution of hydroxyl anions with S anion caused by the polarization effect. As such, the incorporation of S into the NiFe(OH)_x can effectively modulate the electronic structure by anionic regulation and generation of S/O hetero-anionic structure with the formation of FeNiS_x on the surface of NiFe(OH)_x, which should be beneficial to the electrocatalytic activity.

Figure 3.6 (a) Raman spectra of NiFe(OH)_x and FeNiS_x/NiFe(OH)_x; (b) Survey spectrum; and high-resolution XPS spectra of (c) Ni 2p, (d) Fe 2p, (e) O 1s and (f) S 2p.

3.3.2 Electrocatalytic performance for OER in alkaline freshwater

Performance of as-prepared electrocatalysts for OER in alkaline freshwater solution was investigated at first in a three-electrode system in 1 M KOH freshwater solution. Figure 3.7a shows the polarization curve of FeNiS_x/NiFe(OH)_x/NF electrode comparing with the related ones as well as benchmark RuO₂ based electrode. To avoid the influence of the oxidation peak on the overpotential range of 1.3-1.5 V (vs. RHE), a high current density was employed for the comparison of overpotentials. As shown in

Figure 3.7b, the FeNiS_x/NiFe(OH)_x/NF electrode exhibits superior performance with a lowest overpotential of 277 mV at 100 mA cm⁻², which is much lower than those of NiFe(OH)_x/NF (332 mV), Ni_xS_y/NF (410 mV) and RuO₂/NF (407 mV) electrodes, indicating that the sulfurization effectively improves the intrinsic activity of NiFe(OH)_x, reduces the free energy between O* and OOH*, and optimizes the Ni- and/or Fe-O bonding, which are beneficial for the improving of OER activity. While, the corresponding Tafel slopes are also calculated from the LSV curves, and as shown in Figure 3.7c, the Tafel slope of FeNiS_x/NiFe(OH)_x/NF electrode is 35.3 mV dec⁻¹, which is much lower than those of NiFe(OH)_x/NF (40.3 mV dec⁻¹), Ni_xS_y/NF (48.3 mV dec⁻¹), bare NF (70.4 mV dec⁻¹) and RuO₂/NF (46.5 mV dec⁻¹) electrodes, suggesting that the FeNiS_x/NiFe(OH)_x/NF electrode results in a fastest kinetic reaction since the S incorporation effectively improves the electronic structure of electrode, thereby adjusting the adsorption/desorption energy on the electrode surface and reducing the gap between the free energy of formation of the O* and OOH* intermediates [31]. EIS analysis was further performed to determine the charge transfer resistance (*R*_{ct}) on the electrode. Nyquist plots in Figure 3.7d reveal that the *R*_{ct} of FeNiS_x/NiFe(OH)_x/NF electrode (0.4 Ω) is also much lower than those of other electrodes such as NiFe(OH)_x/NF (0.6 Ω), indicating that the incorporation of S effectively improves the conductivity and the *in-situ* growth with sulfurization strategy also effectively reduces the charge transfer resistance between electrocatalyst layer and substrate. In addition, the electrochemical active surface areas (ECSAs) calculated from the double layer capacitances (*C*_{dl}) by measuring cyclic voltammetry at different scan rates (Figure 3.7e) show that the FeNiS_x/NiFe(OH)_x electrocatalyst has the highest *C*_{dl} value of 9.2 mF cm⁻², which is approximately 1.2 times higher than those of NiFe(OH)_x. This result also

indicates that the sulfurization improves the ECSA significantly by increasing the surface area and exposing/generating more active sites.

A multi-step chronopotentiometry test was carried out to identify the stability of FeNiS_x/NiFe(OH)_x electrocatalyst. As can be seen from Figure 3.7f, the current density is increased from 100 mA cm⁻² and ended at 1,000 mA cm⁻² with an increment of 100 mA cm⁻² per 600 s, the relating potential at each condition remains constant without any fluctuation. Moreover, the reverse operation by changing the current density back to 100 mA cm⁻² from 1,000 mA cm⁻² also exhibits the same initial potential response as the initial process at the same current density, demonstrating superior mechanical robustness throughout a wide range of current densities, which indicates its applicable for a practical process.

The durability of FeNiS_x/NiFe(OH)_x/NF electrode for OER in alkaline freshwater solution containing 1 M KOH was further investigated by cyclic voltammetry at a scan rate of 100 mV/s for 2000 cycles as well as chronopotentiometry at a constant current density of 100 mA cm⁻² for 100 hours. As can be seen in Figure 3.7g, the LSV curves before and after the accelerated degradation test are identical after 2,000 cycles, suggesting high mechanical robustness. While, as indicated in Figure 3.7h, the FeNiS_x/NiFe(OH)_x/NF electrode maintains its initial potential for at least 100 h without the degradation, confirming its superior activity and stability of this electrocatalyst in alkaline solution compared to the NiFe based ones (Table 3.1). Figure 3.7i shows the morphology of spent electrocatalyst after the 100-h stability test. One can see that the nanosheet structure maintains almost unchanged after the long-time stability test. The presence of Ni, Fe, and S on the spent electrocatalyst is also confirmed (Figure 3.8). The XRD analysis indicates the amorphous nature of the spent electrocatalysts (Figure 3.9a). Furthermore, the XPS analysis (Figure 3.10) also displays that the composition

and oxidation states of the main elements in the spent electrocatalyst remain almost unchanged. Especially, the Fe 2*p* profile at 708.7 eV corresponding to Fe⁰ is still retained, implying that the chemical composition and the valence state are not changed after the stability test.

3.3.3 Selectivity of OER performance in alkaline simulated seawater

The OER performance of the FeNiS_x/NiFe(OH)_x/NF electrode in an alkaline simulated seawater electrolyte was further investigated by adding 0.5 M NaCl into 1 M KOH freshwater solution [34]. As shown in Figures 3.11(a-b), only overpotentials of 270, 440 and 614 mV are required to achieve current densities of 100, 500 and 1,000 mA cm⁻², respectively, which are even slightly better than the case using alkaline freshwater solution containing 1 M KOH, and better performance than those recently reported electrocatalysts for seawater electrolysis (Table 3.2). Multi-step chronopotentiometry measurements with various current density inputs were also performed to test its stability working at different environments such as those in the practical process. As shown in Figure 3.11c, notably, this electrode demonstrates a consistent response potential in each step, implying that this electrocatalyst has

excellent mass transfer and charge transfer property as well as stability in the simulated seawater environment over a wide range of current densities. While, as displayed in Figure 3.11d, the electrode can maintain its initial potential of 1.53 V *vs* RHE in the alkaline simulated seawater at 100 mA cm⁻² for 100 hours without degradation and/or corrosion. Moreover, even at a current density of 500 mA cm⁻², it also shows no obvious change comparing to the initial potential after 100-h stability test. In addition, no chlorine gas and hypochlorite are detected and no catalyst dissolution and/or the catalyst peeling off from NF substrate is observed during OER process. Therefore, the prepared FeNiS_x/NiFe(OH)_x/NF electrode has superior durability and high selectivity towards OER in the electrolysis of alkaline simulated seawater. Herein, it should be noted that the overpotential of this electrode is much lower than 480 mV, and the pH value after stability test even at a high current density is around 10, which are the favorable conditions to achieve high selectivity towards OER in a seawater electrolyzer [6]. Moreover, the nanosheet structure of the spent catalyst after the durability test for over 100 h is still maintained (Figures 3.11(e-f)), suggesting the mechanical stability and anti-corrosion of this electrode in simulated seawater solution. Furthermore, as displayed in Figure 3.9b, the XRD pattern of the electrocatalysts after long-term OER stability test is similar to the initial state, showing that the amorphous nature is also stable in the simulated seawater solution. Moreover, as shown in Figure 3.12, except for S species, the chemical valence states of other main elements are essentially unchanged, also indicating the chemical stability of Ni and Fe species. However, for the EDS elemental mapping, it is confirmed that the S element is still remained in the spent electrocatalyst (Figure 3.13). The superior stability of this electrode could be attributed to the intercalating of sulfate ions into the NiFe(OH)_x structure since it can enhance OER activity as well as corrosion resistance to chloride anions in seawater [4].

The generation of multivalent anions such as sulfite during the reaction could enhance cation selectivity and thus block the chloride anions.

To investigate the possibility of this electrode used in an industrial scale condition, the durability test at a constant current density as high as 1 A cm^{-2} was also carried out for 100 h in the simulated seawater solution. Interestingly, as shown in Figure. 3.14a, the prepared $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x/\text{NF}$ electrode also exhibits outstanding stability for over 100 hours without performance drop or catalyst corrosion. Notably, because of the cavitation of produced gas (O_2) and Cl^- in the solution caused by the high current density input, the surface morphology changes after the stability test, implying surface damage [35]. However, the TEM observation (Figure 3.14b) confirms the presence of FeS and $\text{NiFe}(\text{OH})_x$ in the initial form. In the present electrocatalyst, the existing of FeNiS_x and $\text{NiFe}(\text{OH})_x$ should have a synergetic effect to provide stable active species for OER in the alkaline simulated solution, and especially FeNiS_x could improve the electrical conductivity and prevent corrosion by chloride anions whereas the $\text{NiFe}(\text{OH})_x$ accelerates water molecule dissociation step in the electrolysis of simulated seawater, thereby resulting in superior stability in the imitate seawater electrolysis.

Figure 3.11 OER performance of FeNiS_x/NiFe(OH)_x in imitate seawater (1M KOH+0.5M NaCl) electrolysis. S-(Ni,Fe)OOH	0.1 M KOH+0.5 M NaCl	278	100	[21]

3.3.4 Elucidation of the OER mechanism by DFT calculations

The DFT calculations were also carried out to identify the OER mechanism and catalytic active sites on FeNiS_x/NiFe(OH)_x electrocatalyst. Theoretically, the OER

mechanism under alkaline condition can be described by four steps using the following equations: [36]

Where the * denotes catalytic active sites on the catalyst surface while OOH^* , O^* and OH^* represent adsorption intermediates.

The catalytic active sites were studied by DFT calculations using Ni and Fe atoms with S substitutions on the O site. The three models are including $NiFe(OH)_x$, $FeNiS_x-NiFe(OH)_x-Fe$ sites and $FeNiS_x-NiFe(OH)_x-Ni$ sites with refer to single phase $NiFe(OH)_x$, S substitution on O (Fe active sites) and S substitution on O (Ni active sites), respectively, are proposed (Figure 3.15).

Figure 3.15 Structure models of (a) $NiFe(OH)_x$; (b) $FeNiS_x-NiFe(OH)_x-Ni$ sites; and (c) $FeNiS_x-NiFe(OH)_x-Fe$ sites.

According to OER in Figure 3.16a, the intermediates $*OH$, $*O$, and $*OOH$ bound to the active sites through oxygen species with a single bond should be in correspondence with four-electron mechanism. Basically, OER overpotential is directly related to the free energies of the reaction intermediates, especially at the second step

(*OH to *O), and the adsorption free energy difference between *OH and *O is proposed to be the main descriptor for the OER activity [32]. As shown in Figure 3.16b, the transformation of *OH to *O can be defined as a rate determining step due to its larger gap of free energy than other steps. As a result, the Gibbs free energy difference value of FeNiS_x-NiFe(OH)_x-(*Fe) ($\Delta G_{II} = 1.61 \text{ eV}$) is lower than those of FeNiS_x-NiFe(OH)_x-(*Ni) ($\Delta G_{II} = 2.21 \text{ eV}$) and NiFe(OH)_x ($\Delta G_{II} = 1.74 \text{ eV}$), suggesting that Fe sites should be the active sites and S substitution on the O site can effectively reduce the free energy, thereby enhancing the electrocatalytic properties. In other words, S doping can decrease free energy gap between *OH to *O, making OER more efficient (Figure 3.16c). Moreover, Cl⁻ adsorption energy on the Ni and Fe sites in FeNiS_x-NiFe(OH)_x electrode were also calculated by DFT. As shown in Figure 3.16d, the free energy of Cl⁻ adsorption on Ni sites (-3.30 eV) is higher than that on Fe sites (-3.19 eV and -2.65 eV), indicating that Cl⁻ adsorption on Ni sites should be more thermodynamically favorable since it is more negative than that of two Fe sites on FeNiS_x-NiFe(OH)_x-(*Fe). As such, more free available sites on the Fe surface could be provided for OER, implying higher OER selectivity against ClER on the FeNiS_x-NiFe(OH)_x-(*Fe) (Figure 3.17).

Figure 3.16 (a) Schematic illustration for OER mechanism, (b) Gibbs free energy diagram; (c) The energy barrier for *OH to *O transition reaction step and, (d) the energy barrier for Cl^- adsorption.

Figure 3.17 Structure models of Cl^- adsorption ; (a) on Ni sites and (b and c) on and Fe sites in $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$.

3.3.5 Overall alkaline freshwater and seawater electrolysis

Since the obtained $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ electrocatalyst shows excellent performances for the OER in both alkaline freshwater and simulated seawater electrolysis processes, a try was performed by using it as the bifunctional electrocatalyst for the overall alkaline freshwater and seawater electrolysis. Figure 3.18 shows a photo of overall water electrolysis cell. Both HER and OER activities of $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ electrocatalyst are demonstrated in Figure 3.19. It is observed that the potential differences (ΔE) between HER and OER at a current density of 100 mA cm^{-2} are 1.82 and 1.80 V for the electrolysis of alkaline freshwater and simulated seawater, respectively. Comparing to the theoretical decomposition voltage of 1.23 V for water electrolysis, this bifunctional electrode requires only 590 and 570 mV overpotentials for the electrolysis of alkaline freshwater and simulated seawater, respectively, which are even lower than those of the cell with noble metal-based catalysts (i.e., Pt/C and RuO_2).

Figure 3.18 Digital photograph show in O_2 and H_2 gas bubbles on the electrode surface.

Figure 3.19 Electrocatalytic activities of FeNiS_x/NiFe(OH)_x/NF electrode for OER and HER; (a) in alkaline freshwater and (b) in alkaline simulated solution.

Due to the outstanding OER and HER activities of this catalyst, a two-electrode cell by using it for both cathode (+) and anode (-) (denoted as FeNiS_x/NiFe(OH)_x/NF || FeNiS_x/NiFe(OH)_x/NF) was investigated. As can be seen in Figures 3.20a and 3.20d, this electrolysis system only requires a low cell voltage of 1.58 and 1.60 V at 10 mA cm⁻² in the alkaline freshwater and simulated seawater solutions, respectively. Notably, for the alkaline freshwater electrolysis, the cell with the bifunctional FeNiS_x/NiFe(OH)_x/NF electrode exhibits superior performance over other reported ones (Figure. 3.20c NiFe-LDH/(Ni(OH)₂ (1.6 V) [30], Ar-NiCo₂O₄/S (1.63 V) [37], NiFe-(oxy)sulfide (1.64 V) [38], NiFe-LDH (1.70 V) [39] NiFe-LDH/FeCoS₂ (1.74 V) [40], NiFe-LDH/Ni₃S₂ (1.65 V)[41] and Ni-CoS₂ (1.66 V)[42]). While, for the simulated seawater solution electrolysis, it also shows a comparable performance to those reported ones (Figure 3.20f. NiMoN//NiMoN@NiFeS (1.58 V), Karst Ni Foam (1.79 V) and NiFe-NiS_x-Ni//Ni-NiO-Cr₂O₃ (1.56 V) [43]).

Long-term stability test of this two-electrode system was also carried out in both alkaline freshwater and simulated seawater solutions at different constant current densities of 10, 100, 500 and 1,000 mA cm⁻². As shown in Figure 3.20b, constant cell

voltages of 1.58, 2.00, 2.90 and 3.54 V are obtained without electrocatalyst dissolution and apparent degradation for 12 h in the alkaline freshwater solution. Similarly, in the imitate seawater solution, the cell voltages of 1.60, 1.93, 2.41 and 2.81 V are also remained for over 12 h (Figure 3.20e). Particularly, this two-electrode system is capable to sustain stable up to 1 A/cm^2 in the imitate seawater solution with an overall water electrolysis voltage of 2.81 V, achieving a high hydrogen productivity without the catalyst deterioration, which should be attributed to that the polyatomic anion on the anode could block the Cl^- and protect the corrosion of electrode. While, it is reported that the S incorporation into the NiFe(OH)_x structure could decrease OH^* adsorption energy as well as free energy gap between O^* and OH^* for the enhancing OER at a lower overpotential, which is consistent with the above DFT results and those in the literature [32]. Moreover, chronopotentiometry measurements with a power on-off condition was also performed to investigate the stability of this electrolysis system in order to mimic the practical operation condition in the large-scale application using intermittent energy sources such as wind and solar power. As shown in Figure 3.20g, the chronopotentiometry measurements were carried out in a simulated seawater solution by continuously applying a current density of 100 mA cm^{-2} for 1 h, then turning off the current for 0.5 h, and repeating this process for 4 cycles. As a result, the cell voltage remains steady at 1.82 V during the power-on period with a good recovery property in each cycle, implying the stability of electrocatalytic performance and mechanical robustness in an unstable power supply system for seawater electrolysis. Besides, the faradaic efficiency is calculated from theoretical and measured hydrogen and oxygen evolution amounts during the electrolysis in the two-electrode system for overall water electrolysis by using this bifunctional electrode as both cathode and anode. As shown in Figure 3.21, the faradaic efficiencies of hydrogen/oxygen production are

as high as 94/95% and 93/94% in the electrolysis of alkaline freshwater and simulated seawater, respectively. Therefore, it could be one of the most promising candidates for hydrogen production from seawater in a large-scale application using a system as illustrated in Figure 3.20h.

Figure 3.20 (a) LSV curves of two-electrode systems of FeNiS_x/NiFe(OH)_x/NF || FeNiS_x/NiFe(OH)_x/NF and Pt/NF//RuO₂/NF for alkaline freshwater electrolysis at a scan rate of 2 mV/s in 1 M KOH solution; (b) Stability tests at 10, 100, 500 and 1,000 mA cm⁻² for 12 h in alkaline freshwater solution containing 1 M KOH; (c) Comparison of the performances of various bifunctional electrocatalysts in electrolysis of alkaline freshwater solution; (d) LSV curves of alkaline freshwater solution containing 1 M KOH at a scan rate of 2 mV/s in alkaline imitate seawater solution; (e) Stability tests.

Figure 3.21 Theoretical hydrogen and oxygen evolution amounts and the measured gas amounts during the electrolysis in the two-electrode system for overall water electrolysis by using $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x/\text{NF}$ electrode as both cathode and anode; (a,b) in alkaline freshwater (1M KOH) and (c,d) in alkaline simulated seawater (1 M KOH+0.5 M NaCl).

3.4 Conclusions

A $\text{FeNiS}_x/\text{NiFe}(\text{OH})_x$ electrocatalyst with a 2D nanosheet structure is successfully *in-situ* grown on nickel foam by using a facile corrosion engineering process followed by a fast and mild sulfurization step. This electrode exhibits excellent electrocatalytic performance with a low OER overpotential of 270 mV at 100 mA cm^{-2} and remarkable stability even at a large current density of 1 A cm^{-2} without catalyst dissolution and erosion for over 100 h in alkaline simulated seawater solution. Moreover, it can also be served as a bifunctional electrocatalysts for both HER and OER in the electrolysis of seawater. As a result, for the overall seawater electrolysis using a two-electrode system, it is capable to sustain stable up to 1 A/cm^2 in the imitate seawater solution with a cell voltage of 2.81 V, achieving a high hydrogen productivity without the catalyst

deterioration while the faradaic efficiencies of hydrogen and oxygen production are as high as 95% and 94% in the electrolysis of alkaline simulated seawater, respectively. The superior activity and durability of this electrode should be attributed to the synergistic interaction between highly conductive FeNiS_x species and the highly catalytic active sites on both FeNiS_x and NiFe(OH)_x. In particular, the incorporated sulfur species could function as a protective coating layer for the blockage Cl⁻ from the electrolyte, preventing catalyst degradation and/or erosion over the long-term operation under a high current density condition by intercalated it into the NiFe(OH)_x layer instead of Cl⁻. DFT calculations proves that the low energy barrier on FeNiS_x/NiFe(OH)_x makes *OH to *O transition step more kinetically promoted and the bonding between Fe and OER intermediates improved. The DFT calculations reveal that Cl⁻ has a high adsorption energy on the non-active Ni sites, implying that more free available Fe sites can be provided for OER, thereby resulting in a high OER selectivity. Therefore, this economical electrode could be a promising candidate for seawater electrolysis even in an industrial-scale application.

CHAPTER 4 Modification of spinel MnCo_2O_4 nanowire with NiFe-layered double hydroxide nanoflakes for stable seawater oxidation

4.1 Introduction

According to the report of the International Energy Agency, the market share of hydrogen from water electrolysis will reach about 22% in 2050 [1]. Thus, water resource for the electrolysis is becoming more and more important since the fresh water resource is limited in our daily life. In contrast, high-salinity *seawater* accounts for 97% of *total water* reserves on the earth [2]. If seawater can be directly electrolyzed for the hydrogen production, the use of hydrogen in various equipments such as fuel cells can generate freshwater, which will not only save the limited fresh water resource but also solve the freshwater problem in the world [3]. Moreover, the seawater electrolysis is beneficial for the storage of those unstable ocean energy such as offshore wind power and tidal and wave energy [4]. However, unlike the fresh water electrolysis, in the seawater electrolysis, it contains competitive reactions between chlorine evolution reaction (CIER ; $2\text{Cl}^- \rightarrow \text{Cl}_2 + 2e^-$, $E^0 = 1.36 V_{\text{RHE}}$) or hypochlorite generation reaction and oxygen evolution reaction (OER ; $4\text{OH}^- \rightarrow \text{O}_2 + 2\text{H}_2\text{O} + 4e^-$; $E^0 = 1.23V_{\text{RHE}}$) since CIER is more kinetically favorable than OER, especially at a high current density [5]. The difference in electrode thermodynamical potential between CIER and OER is fixed at 0.480 V. The hypochlorite will be not formed if the overpotential is less than 480 mV [6]. Furthermore, considering for a large-scale application at a high current density, catalyst corrosion and degradation should be taken into account. Sometimes, even though there is a lower overpotential, those accumulated Cl^- ions would limit anode lifetime because high-concentration Cl^- ions at the

electrode/electrolyte interface tend to accelerate the corrosion process through metal chloride-hydroxide formation, leading to catalyst deactivation [7]. Therefore, the designing criteria for the electrocatalysts in the seawater electrolysis should be (i) high OER selectivity and stability, (ii) high corrosion resistance, (iii) high temperature tolerance [8], and especially (iv) stable performance at high current density ($\sim 0.4\text{--}1\text{ A cm}^{-2}$).

Spinel-type cobalt-based binary metal oxides such as MnCo_2O_4 [9], CuCo_2O_4 [10], and NiCo_2O_4 [11] have been studied for OER because of their redox stability, synergy of two metals and mixed variance states of each metal. Especially, for MnCo_2O_4 , it has an abundance active sites, in which the cobalt species provides a high oxidation potential while the manganese species affords high electron transfer ability along with defined morphology [12]. However, its performance is still unsatisfactory since it suffers from poor ionic conductivity and partial dissolution in those alkaline electrolytes, resulting in poor stability. Many strategies have been proposed to improve OER activity and stability such as modified MnCo_2O_4 with cation substitution [13], anchored on a highly conductive material [14] and surface modification [15]. To date, MnCo_2O_4 has never been used in a seawater electrolysis system [16]. In the presence of chlorine ions, it is reported that MnO_x based catalysts always have high OER selectivity since MnO_x can block Cl^- transportation [17, 18]. While, it is found that some Layered Double Hydroxide (LDH) materials also have the ability to block chlorine ions due to higher Cl^- adsorption free energy on their surfaces [19]. Among those LDH materials, NiFe-LDH is the most active one for the OER in alkaline electrolytes. However, inferior electrical activity, limited active sites, intrinsically poor catalytic activity, metal dissolution and instability during the OER at current densities higher than 100 mA cm^{-2} are the key barriers for industrial applications [20]. Recently,

it is found that uniformly coating of NiFe-LDH on a sulfide layer formed on a nickel substrate led to superior catalytic activity and corrosion resistance in alkaline seawater electrolysis [21]. Inspired by these reported results, in this study, modification of the MnCo_2O_4 nanowire with a NiFe-LDH layer was proposed in the preparation of electrocatalysts for the stable seawater electrolysis. It is expected that the combination of NiFe-LDH active material with Cl^- blocking property and MnCo_2O_4 with rich active sites could significantly boost the activity and extend the stability in seawater electrolysis due to the synergy effect between the two materials.

4.2 Experimental section

4.2.1 Chemical and materials

Manganese (II) nitrate tetrahydrate ($\text{Mn}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, $\geq 97\%$) and ruthenium (IV) oxide (RuO_2 , 99.9%) were purchased from Sigma-Aldrich, Japan. Cobalt (II) nitrate hexahydrate ($\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, 99.5%), ammonium fluoride (NH_4F , 97%), urea ($\text{CH}_4\text{N}_2\text{O}$, 99%), iron (III) chloride hexahydrate ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, 99%), sodium nitrate (NaNO_3 , 99%), sodium chloride (NaCl , 99%) hydrochloric acid (HCl , 69%), potassium hydroxide (KOH , 85%) and ethanol ($\text{C}_2\text{H}_5\text{OH}$, 99.5%) were purchased from Wako, Japan. Deionized (DI) water (18.2 $\text{M}\Omega \text{ cm}$) was used to prepare the solution. Nickel foam (NF; 1.5 mm of thickness, 0.23 g/cm^3 bulk density and 110 pores/inch) was purchased from MTI, Japan.

4.2.2 Preparation of MnCo_2O_4 @NiFe-LDH on nickel foam (NF)

To remove oxide layer and other impurities, NF sheet ($2 \times 2 \text{ cm}^2$) was ultrasonically cleaned in 1 M HCl , ethanol and deionized water consecutively for 1 h in each step, and then dried for 1 h in a vacuum oven at 60 $^\circ\text{C}$. For the preparation of MnCo_2O_4 @NiFe-LDH on the NF, 1 mmol of $\text{Mn}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 2 mmol of $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, 6 mmol of NH_4F and 12 mmol of $\text{CH}_4\text{N}_2\text{O}$ were dissolved in 30 ml of DI water, and then the pre-

treated NF sheet was immersed into the above solution in a Teflon-lined autoclave, which was heated for 4 h at 120 °C followed by naturally cooling down. The resulting electrode was rinsed with ethanol and DI water successively, dried in vacuum oven at 60 °C for 12 h, and continuously calcined in air atmosphere at 350 °C for 2 h. As such the MnCo₂O₄ nanowires were formed on the NF substrate. The obtained MnCo₂O₄/NF was then placed in an autoclave with a solution containing 2 mmol of FeCl₃·6H₂O and 2 mmol of NaNO₃ in 30 ml of DI water, which was heated at 120 °C for 2 h. Thereafter, the obtained electrode was rinsed with DI water and ethanol successively for 3 times before being dried in a vacuum oven at 60 °C for 12 h. As such, the NiFe-LDH nanosheets were deposited on each MnCo₂O₄ nanowire was obtained, which is denoted as MnCo₂O₄@NiFe-LDH@NF electrode. For comparison, MnCo₂O₄/NF and NiFe-LDH/NF electrodes were also prepared by using the same hydrothermal method.

4.2.3 Catalyst characterization

A scanning electron microscope (SEM, SU8010, HITACHI, JAPAN) and a transmission electron microscope (TEM, JEM-2100F, JEOL) were used to examine the morphology and nanostructure of the prepared electrocatalysts, respectively. The phase compositions and crystalline structures were characterized by an X-ray photoelectron spectroscopy measurement (XPS) using a VG Scientific ESCALab250i-XL instrument with an Al-K α X-ray source and X-ray diffraction (XRD) measurement in a 2 θ range of 10°-80° with a Rigaku Smartlab diffractometer (Japan) using a Cu-K α radiation source (λ = 0.15406 nm), respectively.

4.2.4 Electrochemical measurements

All prepared electrodes were examined using a three-electrode system on an electrochemical workstation (Versa STAT4, Princeton, USA). A standard Hg/HgO electrode was used as the reference electrode, a carbon rod was used as the counter

electrode and the as-prepared electrode was used directly as the working electrode. The potential with respect to reversible hydrogen electrode (RHE) was calculated by the Nernst equation: $E(\text{V vs. RHE}) = E(\text{V vs. Hg/HgO}) + 0.098 + 0.059\text{pH}$. The corresponding overpotential (η) for OER was calculated using the formula: $\eta = E(\text{vs RHE}) - 1.23 \text{ V}$. The polarization curve was measured in a potential range of 0.924-2.324 V vs RHE at a scan rate of 2 mVs^{-1} in both a simulated seawater alkaline solution (1 M KOH + 0.5 M NaCl) and a natural seawater based alkaline solution (the natural seawater was collected from Pacific Ocean, Aomori Prefecture, Japan) without iR-compensation. The electrochemical impedance spectroscopy (EIS) measurement was performed at a frequency range of 100 kHz-0.1 Hz. The cyclic voltammetry (CV) was conducted in a potential range of 0.1-0.2 V at a scan rate range of 10-100 mVs^{-1} to determine the electrochemical double layer capacitance (C_{dl}) for the determination of electrochemical active surface area (ECSA). OER durability was evaluated by using the chronopotentiometry testing for 20 h. at 10°C with constant high current densities of 100 and $1,000 \text{ mA cm}^{-2}$ in an alkaline simulated seawater solution (1M KOH + 0.5M NaCl).

4.3 Results and discussion

4.3.1 Characterization of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst

A two-step hydrothermal method was used to prepare the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst on NF (Figure 4.1a). As shown in Figure 4.1b, the MnCo_2O_4 nanowires have been successfully grown on the surface of NF substrate. Then, the NiFe-LDH layer has been also deposited on the MnCo_2O_4 nanowire via a reduction reaction between NaNO_3 and FeCl_3 : $\text{NO}_3^- + \text{H}_2\text{O} + 2e^- \rightarrow \text{NO}_2^- + 2\text{OH}^-$, where the OH^- results in the precipitation of Ni and Fe species to form NiFe-LDH nanosheets on the surface of each nanowire (Figure 4.1c) [22]. One can see that the NiFe-LDH nanosheets are fully

covered on the surface of each MnCo_2O_4 nanowire (Figure 4.1d). The presences of Mn, Co, Ni, Fe and Ni elements on the NF have been also confirmed by the EDS elemental mapping (Figures. 4.1e-j). Fig. 2a shows the XRD patterns, on which the peaks at 18.8° , 31.0° , 36.5° , 38.2° , 44.4° , 54.8° , 58.3° and 64.2° are contributed to the (111), (220), (311), (222), (400), (422), (511) and (440) planes of MnCo_2O_4 with cubic spinel structure (JCPDS 23-1237) whereas the peaks corresponding to the NiFe-LDH are well matching with the typical pattern (JCPDS 38-0715) [23]. Herein, the observed shoulder peaks at 10° and 78° are the main characteristic peaks of NiFe-LDH, confirming the generation of NiFe-LDH on the MnCo_2O_4 .

TEM image of the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (Fig. 2b) clearly indicate a MnCo_2O_4 core with a NiFe-LDH shell structure. The lattice spacings of 0.29 and 0.23 nm in Figs. 2c-d are consistent with the (220) and (015) planes of MnCo_2O_4 and NiFe-LDH, respectively [24]. One can see that the coating of NiFe-LDH nanoflakes on the MnCo_2O_4 nanowire causes defects on the parent MnCo_2O_4 , which could promote electrochemical activity due to the generation of active sites as well as oxygen vacancies with the modifying of the electronic structure. Herein, the strong chemical bonding between metal species and absorbed oxygen species on the oxygen vacancy sites could facilitate oxygen activation and partial dissociation of the adsorbed H_2O molecules [25].

Figure 4.1 Fabrication and characterizations of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst. (a) Schematic illustration of the fabrication route of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}/\text{NF}$ electrode; (b) SEM surface images of $\text{MnCo}_2\text{O}_4/\text{NF}$, (c) $\text{NiFe-LDH}/\text{NF}$, and (d) $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}/\text{NF}$; and (e-j) EDS elemental mappings of Mn, Co, Fe, Ni and O elements.

Figure 4.2 (a) XRD patterns and (b) TEM image with a low magnification of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$; (c-d) HR-TEM images of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$.

Figure 4.3 shows the XPS spectra of as-prepared $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst (Figure. 4.3a). The deconvolution peaks for the parent MnCo_2O_4 nanowires (Figure. 4.3b) confirm the presence of Mn^{2+} (641.7 and 653.0 eV) and Mn^{3+} (643.6 and 654.5 eV) species. The Co 2p spectra show two spin-orbital doublets at 780.4 and 795.5 eV, which are attributed to Co 2p_{3/2} and Co 2p_{1/2} of Co^{3+} , respectively [26]. While, the peaks at 782.5 and 797.6 eV are related to Co 2p_{3/2} and Co 2p_{1/2} of Co^{2+} , respectively (Figure 4.3c). As shown in Figure 4.3d, the binding energies of 855.7 and 873.3 eV are ascribed to Ni 2p_{3/2} and Ni 2p_{1/2}, which correspond to Ni^{2+} of NiFe-LDH [27]. As summarized in Table 4.1, the relative ratio of Mn^{3+} was reduced with the increases in that of Mn^{2+} after the growing of NiFe-LDH nanosheets on MnCo_2O_4 nanowire due to the chemical reduction process. Furthermore, the peak of Co 2p 3/2 shifts toward the lower binding energy direction, indicating that Fe incorporation changes the electronic structure of Co species in comparison to the pure MnCo_2O_4 (Figure 4.3c). Notably, the relative ratio of Co^{3+} species is increased after the growth of NiFe-LDH, implying an increase in OER active sites [29]. Most importantly, as indicated in Table 1, the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ has a higher $\text{Co}^{3+}/\text{Co}^{2+}$ ratio (1.32) than MnCo_2O_4 (1.21), implying a higher OER activity for the promoting of water dissociation to active OH^* intermediate species and the accelerating of OER kinetics [30]. While, a higher $\text{Ni}^{3+}/\text{Ni}^{2+}$ on the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (0.83) than that on the NiFe-LDH (0.79) could lower the overpotential of the electrode for OER because higher Ni^{3+} concentration on the electrocatalyst is beneficial for the OER with Fe^{3+} . However, as shown in Figures 4.3d-e, it should be noted that the oxidation states of Ni and Fe species are not noticeably changed comparing to those on the initial NiFe-LDH. According to the report by Steven *et al.*[31], only those surface Fe^{3+} species at the edge/defect sites could be responsible for the enhancement of OER activity relating to

Ni²⁺ species. Based on the above XPS analysis results, the incorporation of NiFe-LDH could effectively improve electrocatalytic activity of MnCo₂O₄. In addition, the O 1s spectrum (Figure 4.3f) can be fitted into three characteristic peaks at 530.0, 531.1 and 532.0 eV, which agree well with the binding energies of lattice oxygen (O_L), oxygen vacancies (O_v) and surface adsorbed water (O_{ads}), respectively [32]. Interestingly, the concentration of O vacancies (O_v) is increased after the incorporation of NiFe-LDH on MnCo₂O₄, implying that more O vacancies have been formed on the electrocatalyst. Herein, the positive shift of O 1s might be caused by the interaction between NiFe-LDH and MnCo₂O₄. Notably, the electronic configuration of MnCo₂O₄ is changed through the incorporation of NiFe-LDH, which could also significantly improve the OER activity due to the synergistic effect of Ni²⁺ and Fe³⁺ on the promoting of surface OER dynamics [19, 33]. In conclusion, the multiple oxidation states in MnCo₂O₄@NiFe-LDH composite electrocatalyst should have rich redox characteristics, resulting in higher activity.

Figure 4.3 XPS spectra of the as-prepared electrocatalysts. (a) Survey spectra, (b) Mn 2p, (c) Co 2p, (d) Ni 2p, (e) Fe 2p and (f) O 1s.

Table 4.1 Elemental valence states of Mn, Co, Ni, Fe and O species of as-prepared electrocatalysts and their relative percentage ratios based on the deconvolution of peak areas.

Catalyst	Peak area ratio of Mn species (%)	Peak area ratio of Co species (%)	Peak area ratio of Ni species (%)	Peak area ratio of Fe species (%)	Relative ratio of O1s peak area (%)
	Mn ²⁺ /Mn ³⁺	Co ²⁺ /Co ³⁺	Ni ²⁺ /Ni ³⁺	Fe ²⁺ /Fe ³⁺	O ²⁻ /OH ⁻ /H-O-H
MnCo ₂ O ₄ /NF	55.4/44.6	45.2/54.8	-	-	47.8/25.9/26.3
NiFe-LDH/NF	-	-	55.8/44.2	50.3/49.7	34.6/36.2/29.2
MnCo ₂ O ₄ @Ni Fe-LDH@/NF	64.6/35.4	43.0/57.0	54.5/45.5	62.0/38.0	26.1/45.8/28.1

Note: The ratios of elemental valence states were calculated by the deconvoluted peak areas from XPS spectra.

4.3.2 Electrochemical performance for OER

The electrocatalytic activity was measured in 1 M KOH containing 0.5 M NaCl solution as the simulated seawater electrolyte [21] and compared with the RuO₂ benchmark electrocatalyst for OER. To avoid the influence of the oxidation peak at the potential range of 1.3-1.4 V (*vs* RHE), a high current density at 100 mA/cm² is employed for the comparison of overpotentials in this study. As shown in Figure 4a, the MnCo₂O₄@NiFe-LDH composite electrocatalyst based electrode exhibits the superior performance with a lowest overpotential of 219 mV, which is lower than those of MnCo₂O₄/NF (395 mV), NiFe-LDH/NF (285 mV), and RuO₂/NF (362 mV) electrodes at the current density of 100 mA cm⁻². These results suggest that the modification of MnCo₂O₄ with NiFe-LDH greatly can improve the electrocatalytic activity for OER. The corresponding Tafel slopes were calculated based on the LSV curves (Fig. 4b). One can see that the Tafel slope of the MnCo₂O₄@NiFe-LDH/NF electrode is 45.4 mV dec⁻¹, which are lower than those of MnCo₂O₄/NF (115.8 mV dec⁻¹), NiFe-LDH/NF (56.4 mV dec⁻¹) and RuO₂/NF (75.4 mV dec⁻¹), indicating that the OER over the MnCo₂O₄@NiFe-LDH has a fastest kinetics, and more oxygen intermediates could be adsorbed on it. Generally, the OER on the catalysts in the alkaline solution could occur as follows [34, 35]:

For the MnCo₂O₄@NiFe-LDH/NF electrode, since its Tafel slope was 45.4 mV dec⁻¹, the possible OER over it could follow Eqs. (1), (2), (4) and (5). That is, the reaction

starts with the adsorption of OH^- in alkaline solution on metal sites (M) on the surface of $MnCo_2O_4@NiFe-LDH$. Then, MOH_{ads} undergoes a proton coupling electron transfer process, transforming into MO_{ads} . The following O-O bond formation step allows MO_{ads} to react with another water molecule to form $MOOH$. Finally, $MOOH$ is oxidized, resulting in the release of O_2 and the recovery of an initial metal active site on the surface of electrode. Considering for the surface adsorption sites of electrode, the XPS analysis reveals that more O vacancy sites are generated on the $MnCo_2O_4@NiFe-LDH$, which could promote the separation of H atoms from MOH_{ads} (Eq. 2) and the formation of $FeOOH$, thereby improving OER kinetics [36-38].

In order to reveal the charge transfer resistance (R_{ct}), the electrochemical impedance spectroscopy was further analysed in a frequency range of 100 kHz-0.1 Hz (Figure 4.4c). One can see that the charge transfer resistance (R_{ct}) of the $MnCo_2O_4@NiFe-LDH/NF$ electrode (0.56 Ω) is lower than those of $MnCo_2O_4/NF$ (0.65 Ω) and $NiFe-LDH/NF$ (0.60 Ω). In addition, the $MnCo_2O_4@NiFe-LDH/NF$ electrode also showed the smallest solution resistance (R_s) of 0.32 Ω , demonstrating the superior conductivity over other electrodes. Therefore, the $MnCo_2O_4@NiFe-LDH/NF$ electrode had a lowest charge transfer resistance with a better electronic property, which led to a faster reaction rate.

The performances of the $MnCo_2O_4@NiFe-LDH/NF$ electrode were further investigated at different operating temperatures. As shown in Figure 4.4d, when the operating temperature was increased from 10 to 80°C, the overpotential of the $MnCo_2O_4@NiFe-LDH/NF$ electrode decreased to some extent (also see: Figure 4.5 and Table 4.2). Notably, this electrode can remain stable until the temperature was raised to 80 °C. In addition, this electrode worked stably at 80 °C for 14 h at a high current density of 100 mA cm⁻² (Figure 4.6), suggesting that it is applicable even at a high operating temperature as well as a large current density.

A multi-step chronopotentiometry test was used to assess the mechanical robustness of this electrode, in which the current density was increased from 100 until 1,000 mA cm⁻² with an increment of 100 mA cm⁻² every 600 seconds. As shown in Figure 4.4e, the response potential remains steady without any fluctuation in each step whereas the reverse process also exhibits the same initial potential response as the forward process, indicating superior mass transport properties and mechanical robustness over a wide range of current densities, which is very important for a practical process.

Additionally, the electrochemical active surface area (ECSA), which was calculated from the double layer capacitance (C_{dl}) measured using the cyclic voltammetry at various scan rates (Figure 4.4f). One can see that the MnCo₂O₄@NiFe-LDH electrocatalyst has a highest C_{dl} value of 12.0 mF cm⁻², which is higher than those of MnCo₂O₄ (9.4 mF cm⁻²) and NiFe-LDH (6.7 mF cm⁻²), implying that this MnCo₂O₄@NiFe-LDH electrocatalyst has higher active surface area, allowing more active sites to be exposed for the facilitating the formation of more oxygen-containing intermediates during the OER process.

Figure 4.4 OER performance in simulated alkaline seawater solution (1 M KOH+0.5 M NaCl solution). (a) LSV curves; (b) Tafel plots; (c) EIS Nyquist plots; (d) LSV curves of the MnCo₂O₄@NiFe-LDH/NF electrode working at different temperatures; (e) Multiple-step chronopotentiometry test; (f) Capacitive current density as a function of scan rate; (g) Chronopotentiometry response at a constant current density of 100 mA cm⁻²; (h) Chronopotentiometry response at an industrial-level constant current density of 1,000 mA cm⁻² for 20 h; and (i) SEM surface image of the spent MnCo₂O₄@NiFe-LDH/NF electrode after the stability test.

Figure 4.5 Overpotentials of OER over MnCo₂O₄@NiFe-LDH electrocatalyst at room temperature (~10°C), 25 °C, 60 °C and 80 °C in alkaline simulated seawater solution.

Figure 4.6 Durability test of MnCo₂O₄@NiFe-LDH/NF electrode for OER at 80 °C in alkaline simulated seawater solution for 14 h.

In addition, the stability was also evaluated for 20 hours using a chronopotentiometry test at a constant current density of 100 mA cm^{-2} . It is found that all the prepared electrodes maintain stable (Figure 4.4g). In order to examine the feasibility of such electrodes for an industrial process, the durability test at 1 A cm^{-2} were also investigated [39]. As shown in Figure 4h, the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}/\text{NF}$ electrode remains its initial potential in the alkaline simulated seawater at 1 A cm^{-2} for 20 h without degradation and potential drop. In comparison, the $\text{MnCo}_2\text{O}_4/\text{NF}$ electrode showed unstable potential especially in the first 5-h testing (Figure 4.4h). Herein, it is found that the fluctuating potentials of the $\text{MnCo}_2\text{O}_4/\text{NF}$ electrode were caused by the dissolution of MnCo_2O_4 in the solution containing NaCl (Figure 4.7). However, after the covering of NiFe-LDH nanosheets on the surface of MnCo_2O_4 nanowire, the catalyst degradation or MnCo_2O_4 dissolution problems can be well solved. It is considered that the NiFe-LDH layer on the MnCo_2O_4 can serve as a Cl^- diffusion barrier to protect the MnCo_2O_4 nanowires from Cl^- erosion while it allows the diffusion of other ions and O_2 transportation between electrode and electrolyte. Furthermore, after the stability test, the spent $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst retains its initial morphology (Figure 4.4i), also implying its high mechanical robustness and tolerance in the harsh conditions.

Table 4.2 Electrocatalytic activity of the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocataly at different temperatures in alkaline simulated seawater solution (1 M KOH+0.5 M NaCl)

Temperature (°C)	η_{100} (mV)	η_{500} (mV)
RT (~10 °C)	222	478
25 °C	154	437
60 °C	137	331
80 °C	124	294

4.3.3 Electrochemical performance for OER in alkaline natural seawater

The OER performance of MnCo₂O₄@NiFe-LDH/NF electrode in an alkaline natural seawater (1 M KOH + Natural seawater, pH = 13.7) was also investigated (Figure 4.8). As presented in Figure 4.8a, the MnCo₂O₄@NiFe-LDH/NF electrode shows low overpotentials of 245 and 578 mV at current densities of 100 and 500 mA cm⁻², respectively. Notably, as shown in Figure 4.8b, the overpotentials are slightly higher than those evaluated in the simulated seawater, which should be due to the existence of some impurities in the natural seawater, especially those insoluble precipitates such as Ca(OH)₂ and Mg(OH)₂ formed in the alkaline natural seawater condition could poison the electrode, resulting in the decrease in the performance for OER (Figure 4.8b) [40].

However, this electrode is still highly durable in the alkaline natural seawater more than 25 h at a relatively high current density of 100 mA cm⁻² (Figure 4.8c). According to the theoretical calculations in the previous report [19], the higher Cl⁻ adsorption energy on the surface of NiFe-LDH could make ClER more difficult to occur, which can simultaneously prevent inner MnCo₂O₄ corrosion from Cl⁻ ions and improve anti-corrosion property, thereby enhancing the stability of such catalysts in the natural seawater based electrolytes.

Figure 4.8 (a) OER performances of the MnCo₂O₄@NiFe-LDH/NF electrode in simulated seawater (1 M KOH+0.5 M NaCl) and alkaline natural seawater (1 M KOH + Natural seawater); (b) Comparison of overpotentials based on the results shown in Figure 4.8a; and (c) Chronopotentiometry response at a high current density of 100 mA cm⁻² for 25 h in alkaline natural seawater solution.

The XPS analysis of the spent electrocatalysts after the stability test was further performed. From the high resolution XPS spectra in the Mn 2p regions (Figure 4.9a), the peaks relating to the Mn²⁺ species decreases whereas those corresponding to Mn³⁺ species increased after the OER reaction, implying partial oxidation of the electrocatalyst during the OER (also see: Table 4.3). While, the relative ratio of Co³⁺/Ni³⁺ (Figures 4.9b-c) were slightly changed. In addition, the relative peak area of Fe³⁺ species increased, suggesting the formation of FeOOH active species during the OER process (Figure 4.9d). Moreover, the characteristic peaks of O 1s spectra of the spent catalysts in both cases corresponding to the lattice oxygen (Figure 4.9e) shift to higher binding energy, indicating the oxidation of lattice oxygen (O_L) (Table 4.3). These surface lattice sites can be exposed to adsorb the intermediates, resulting in lower kinetic barriers, which is better for OER activity [41].

Similar phenomena were also reported by Huang *et al.*, in which they implied that the optimal activity could be tuned via a barrier symmetry regulation between O-H bond cleavage and OOH* formation on the lattice oxygen sites, which can improve the OER

performance [42]. While, as stated above, the Mn^{3+} , Co^{3+} , Ni^{3+} , and Fe^{3+} with higher oxidation states could also play an important role in maintaining the excellent durability in the alkaline natural seawater solution. Moreover, as indicated by Cheng *et al.* [43], chloride ions could act as a bridge ligand between Co and Fe by inserting into the interlayer of CoFe-LDH, which can stabilize the higher valence state of the Co element for retaining active sites for OER. In this study, for the NiFe-LDH, the similar function could also exist for the improving of OER in the alkaline natural seawater solution.

The SEM image (Figure 4.9f) also shows that the MnCo_2O_4 nanowire coated with NiFe-LDH nanosheet structure is well maintained after the stability test, indicating its mechanical stability in the alkaline natural seawater solution during the OER process.

Figure 4.9 XPS spectra of the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst before and after OER stability test in the alkaline simulated and natural seawater solutions: (a) Mn 2p, (b) Co 2p, (c) Ni 2p, (d) Fe 2p, (e) O 1s; and (f) SEM image after the long-term stability test in alkaline natural seawater solution.

Moreover, TEM images (Figures 4.10(a-f)) confirm that the lattice fringe of (015) plane of NiFe-LDH and (220) plane of MnCo_2O_4 are remained. Interestingly, the crystal lattice of Fe-OOH can be observed due to the surface reconstruction of NiFe-LDH during the OER process, indicating that NiFe-LDH lattice distortion can accelerate the formation of Fe-OOH active species (Figures 4.10(g-i)) [44]. Based on these results, the present core-shell structure with two synergetic electrocatalytic components can effectively endow the catalyst with high activity and stability, which is ranked the top-level in the developed OER electrocatalysts for seawater electrolysis (Table 4.4).

Figure 4.10 TEM images of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ after the stability test: (a-b) $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$; (c) NiFe-LDH layer; (d) lattice distance of NiFe-LDH layer; (e) MnCo_2O_4 layer; (f) lattice distance of MnCo_2O_4 ; (g-h) Fe-OOH; and (i) Lattice distance of Fe-OOH.

Table 4.3 Elemental valence states of Mn, Co, Ni, Fe and O species of spent $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst after the stability test comparing with the fresh one and their relative percentage ratios based on the deconvolution of peak areas.

Catalyst	Peak area ratio of Mn species (%)	Peak area ratio of Co species (%)	Peak area ratio of Ni species (%)	Peak area ratio of Fe species (%)	Relative ratio of O1s peak area (%)
	$\text{Mn}^{2+}/\text{Mn}^{3+}$	$\text{Co}^{2+}/\text{Co}^{3+}$	$\text{Ni}^{2+}/\text{Ni}^{3+}$	$\text{Fe}^{2+}/\text{Fe}^{3+}$	$\text{O}^{2-}/\text{OH}^-/\text{H-O-H}$
$\text{MnCo}_2\text{O}_4@\text{NiFe}$ -LDH - initial	64.6/35.4	43.0/57.0	54.5/45.5	62.0/38.0	26.1/45.8/28.1
$\text{MnCo}_2\text{O}_4@\text{NiFe}$ -LDH - after the stability test in alkaline simulated seawater solution	57.0/43.0	48.2/51.8	58.7/41.3	46.5/53.5	34.9/35.9/29.2
$\text{MnCo}_2\text{O}_4@\text{NiFe}$ -LDH - after the stability test in alkaline natural seawater solution	52.3/47.7	41.5/58.5	56.9/43.1	47.9/52.1	31.6/39.6/28.8

Moreover, the HER performance of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ was also investigated. As shown in Figure 4.11, $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ exhibits the lowest overpotential as 90 mV at the standard current density of 10 mA cm^{-2} . Finally, overall seawater electrolysis was performed by using $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ as the bifunctional electrocatalyst for both anode and cathode ($\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (-) || $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (+), which requires low cell voltages of 1.54 and 1.56 V at the standard current density of 10 mA cm^{-2} in the alkaline simulated and natural seawater solutions, respectively. Furthermore, its initial potentials can be maintained for 100 h at

a relatively high current density of 100 mA cm^{-2} without degradation or catalyst corrosion (Figures 4.12(a-c)). It confirms that such an electrocatalyst can also serve as the bifunctional electrocatalyst for seawater electrolysis with high stability against chloride corrosion.

Figure 4.11 LSV curves for HER over $\text{MnCo}_2\text{O}_4/\text{NF}$, NiFe-LDH and $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}/\text{NF}$ electrocatalyst at room temperature in alkaline simulated seawater solution.

Figure 4.12 (a) LSV curves of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (-) || $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (+) cell in the alkaline simulated and natural seawater solutions; (b) Chronopotentiometry test of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (-) || $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ (+) cell at a high current density of 100 mA cm^{-2} in the alkaline simulated seawater solution (1 M KOH+0.5 M NaCl) and (c) in the alkaline natural seawater solution (1 M KOH + Natural seawater).

4.4 Conclusions

In summary, a rational design of $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}$ electrocatalyst with a core@shell structure was successfully performed and fabricated on NF substrate via a facile two-step hydrothermal method. The obtained electrode exhibited excellent electrocatalytic performance for OER with low overpotentials as 219 and 245 mV at a relatively high current density of 100 mA cm^{-2} in the alkaline simulated and natural seawater solutions, respectively. Moreover, the $\text{MnCo}_2\text{O}_4@\text{NiFe-LDH}/\text{NF}$ electrode exhibited high stability at different seawater conditions without corrosion even at an industrial scale level ($> 500 \text{ mA cm}^{-2}$). Besides, this electrocatalyst can also serve as the bifunctional electrocatalyst for the seawater electrolysis with high durability against chloride corrosion for over 100 h. The outstanding activity and durability of this electrode should be attributed to that (i) the NiFe-LDH shell on the MnCo_2O_4 core can enhance electron transfer and act as a protective layer against Cl^- erosion ; (ii) the MnCo_2O_4 core can provide rich active sites for OER with the assistance of the NiFe-LDH shell; (iii) the incorporation of NiFe-LDH nanosheets on the MnCo_2O_4 core can effectively increase the active surface area, enhance the charge transfer property of MnCo_2O_4 nanowires, and maintain higher valence states of the Mn, Co, Ni and Fe species in the electrocatalyst, which is beneficial for the retaining of rich active sites for long-term OER; and (iv) the generation of Fe-OOH on the lattice oxygen sites of NiFe-LDH during the OER process can effectively promote water dissociation and reduce the kinetics barrier, thereby improving OER kinetics. Therefore, the synergistic effect between MnCo_2O_4 and NiFe-LDH played a crucial role for maintaining the catalytic activity and stability against chloride corrosion in alkaline natural seawater solution since Cl^- could be inserted into the interlayer of NiFe-LDH, which can stabilize the higher valence state of the Mn^{3+} , Co^{3+} , Ni^{3+} , and Fe^{3+} elements for retaining active sites

for OER and preventing the catalyst corrosion. This pioneer electrode could be a promising candidate for industrial-scale alkaline natural seawater electrolysis.

Table 4.4 Comparison of OER performance of the present electrocatalyst with those recently reported ones for seawater electrolysis

Electrocatalyst	Electrolyte	Overpotential at 100 mA cm ⁻² (mV)	Reference
MnCo ₂ O ₄ @NiFe-LDH	1 M KOH+0.5 M NaCl	219	This work
	1 M KOH + Natural seawater	245	
NiFeN @NiMoN	1 M KOH+0.5 M NaCl	286	[37]
NiFe-CuCo-LDH	6M KOH seawater	259	[14]
NiFe-NiS _x -Ni activated	1 M KOH+0.5 M NaCl	~300 (at 400 mA/cm ²)	[16]
NiFe LDH/C	0.1 M KOH+0.5 M NaCl	359 (at 10 mA/cm ²)	[38]
FTO/NiO	0.1 M KOH+0.5 M NaCl	340	[39]
S-NiMoO ₄ @NiFe-LDH/NF	1 M KOH+0.5 M NaCl	273	[40]
	1 M KOH + seawater	315

CHAPTER 5 Conclusions and Prospects

5.1 Conclusions

Water splitting is a clean and secure process for producing hydrogen by decomposing water using various power sources such as electrical (current), thermal (heat) and light (electromagnetic radiation). In this study, electricity is used to cleave H-O-H bonds, resulting in the production of hydrogen and oxygen via the HER and OER. The major challenge to the implementation of electrochemical water splitting applications is the energy-efficiency loss with high overpotential during HER, OER and competitive reaction between OER and ClER, as well as economic inefficiencies including high-cost noble metal catalysts used and complicated processes. Additionally, the most important criteria for scaling up the application of electrocatalysts from laboratory scale to industrial scale is related to the catalytic activity, stability, suitability for a wide range of current densities and high corrosion resistance. Therefore, minimizing the production cost but maximizing the performance by three different development strategies are used in this study, including the introduction of O vacancies on transition metal oxides by combining nanoengineering and defect engineering, sulfurized transition metal hydroxides, and nanostructured engineering for spinel oxide modification, to improve intrinsic activity, electrocatalytic activity and stability, especially at high and harsh conditions comparable to industrial scale. The key performances of all electrocatalysts are summarized as follows ;

(1) The obtained $\text{CuVO}_x@\text{NiO}/\text{CP}$ composite electrode is successfully synthesized via a facile hydrothermal process combined with a calcination step. This electrode exhibits a remarkable HER activity in alkaline solution with an overpotential as low as 74 mV at 10 mA cm^{-2} , which also shows excellent stability for 30 hours and a fast

kinetic reaction with a Tafel slope of 60.8 mVdec^{-1} . Moreover, it can work stably in a wide range of current densities ($10\text{-}300 \text{ mA cm}^{-2}$). It is found that real active species are generated during HER due to CuVO_x is reduced to $\text{VO}_x\text{-Cu}_2\text{O/Cu}$ with increased O vacancies. Besides, the NiO shell also improved a number of active sites as well as super-hydrophilic surface, which effectively facilitate the H_2O adsorption and decomposition to H_{ads} intermediates, suggesting accelerate HER performance.

(2) In order to reduce catalyst preparation cost and time and simultaneously decrease interfacial resistance between the electrocatalyst and the substrate, increase electrical conductivity, and prevent electrocatalyst peeling off from the substrate during the long-term operation at a high current density in seawater solution, a simple corrosion engineering process followed by a fast and mild sulfurization step is used for *in-situ* growing of $\text{FeNiS}_x/\text{NiFe(OH)}_x$ composite on nickel foam (NF) substrate. The obtained electrode has an outstanding electrocatalytic activity with a low overpotential of 277 and 270 mV for the OER in alkaline and alkaline simulated seawater at 100 mA cm^{-2} , respectively. Furthermore, it can operate continuously for 100 hours at a current density of 1 A cm^{-2} , which is comparable to industrial scale. Furthermore, this catalyst was used for both anode and cathode in a two-electrode system for overall seawater electrolysis, and it was capable of sustaining stable up to 1 A/cm^2 in the imitate seawater solution with a cell voltage of 2.81 V, achieving a high hydrogen productivity without catalyst deterioration, while the faradaic efficiencies of hydrogen and oxygen production were as high as 95% and 94% in the electrolysis of alkaline simulated seawater. In this study, incorporated sulfur species could function as a protective coating layer for the blockage Cl^- from the seawater electrolyte, preventing catalyst degradation over the long-term operation under a high current density condition by intercalated it into the NiFe(OH)_x layer instead of Cl^- and DFT calculations proves that S substitution on the O site

(NiFe(OH)_x) can effectively lower energy barrier on FeNiS_x/NiFe(OH)_x makes *OH to *O transition step more kinetically promoted, implying improve OER activity. Besides, DFT calculations reveal that Cl⁻ has a high adsorption energy on the non-active Ni sites, implying that more free available Fe sites can be provided for OER, thereby resulting in a high OER selectivity. Therefore, this economical electrode could be a promising candidate for seawater electrolysis even in an industrial-scale application.

(3) A simple two-step hydrothermal method at low temperature is used for synthesized MnCo₂O₄ core @NiFe-LDH shell structure. This electrode exhibits low overpotentials of 219 and 245 mV at a high current density of 100 mA cm⁻² in alkaline simulated and natural seawaters (collected from Pacific ocean, Aomori, Japan), respectively. It is found that the NiFe-LDH function as Cl⁻ protective layer against catalyst corrosion via CLER and active sites for OER, while MnCo₂O₄ nanowires provides a high active surface area and stable core structure. This electrode not only works consistently at room temperature, but also when the temperature is raised to 80 °C for 14 hours at a high current density of 100 mA cm⁻², implying high thermal tolerance in a harsh condition. Moreover, when MnCo₂O₄ @NiFe-LDH is utilized as the bifunctional electrocatalyst for overall seawater electrolysis. It shows a low cell voltages of 1.54 and 1.56V at the standard current density of 10 mA cm⁻² in the alkaline simulated and natural seawater solutions, respectively, and highly stable for 100 hours at a high current density of 100 mA cm⁻² without degradation or catalyst corrosion. In conclusion, the incorporation of NiFe-LDH nanosheets on the MnCo₂O₄ core can effectively increase the active surface area, enhance the charge transfer property of MnCo₂O₄ nanowires, and maintain higher valence states of the Mn, Co, Ni and Fe species in the electrocatalyst, which is beneficial for retaining rich active sites for long-term OER. These outstanding results provide a promising candidate for sustain seawater splitting.

5.2 Prospects

Even though significant efforts have been performed for the developing of the electrocatalysts for water splitting application, most of developed electrocatalysts were rarely used in an industrial scale due to limitations such as durability and catalyst dissolution. Moreover, some parameters require further investigation in order to prove the reaction mechanism.

The following points should be considered for further development of electrocatalysts in order to step up the water electrolysis system to a practical scale;

(1) Alternative corrosion resistance substrates

Currently, carbon paper, nickel foam and copper foam are commonly used as a substrate for water electrolysis application. However, the durability in a wide range of pH values are still unsatisfied. Therefore, seeking for the alternative substrates such as Ti foil, FTO and Iron foam or surface modification of substrate are suggested.

(2) Seeking for novel electrocatalysts with higher performance and low cost

Novel electrocatalysts with higher performance and low cost are still desired. For example, those carbon-based electrocatalysts like MXene and ZIF-67, which are commonly used in supercapacitors and lithium-ion batteries (LIBs), could be also applied in water electrolysis because they can work stably in acid and neutral conditions. While, those developed electrocatalysts such as transition metal oxides/hydroxides, transition metal sulfide, and transition metal phosphide could be further modified so that they can be more suitable for HER/OER in harsh conditions, especially for seawater electrolysis.

(3) More efficient electrocatalysts for seawater electrolysis

How to improve the selectivity and erosion resistance of electrocatalysts for seawater electrolysis is still full of challenges. The way for the detecting of Cl-related products in the seawater electrolysis should be considered for confirming the catalytic selectivity

the chlorine evolution (CIER)

(4) Energy saving hydrogen production system

To complete the life cycle of sustainable development by utilizing abundant natural resources, seawater electrolysis coupling with another system such as sulfion degradation, hybrid seawater electrolyzer with a solar cell, combined with zinc-air battery are interesting for new opportunities in sustainable hydrogen production.

CURRICULUM VITAE

Personal details

Name: NUTTHAPHAK KITIPHATPIBOON
Nationality: THAI
Date of birth: 26 February 1989
Email: nkitiphatpiboon@gmail.com

Educations

April, 2020-March, 2023	D.Eng. (Safety Science and Technology), Hirosaki University, Japan
May, 2012- January, 2015	M.Sc. (Fuel Technology), Chulalongkorn University, Thailand
June, 2007- April, 2011	B.Sc. (Biotechnology), Mahidol University, Thailand

Experiences

September, 2022	Presentation on the event that held by Hirosaki City : Talks about the world directly from internationals students, Hirosaki Museum of Contemporary Art.
August, 2015- August, 2019	Researcher at Kao Consumer Products (Southeast Asia) Co., Ltd.
November, 2013	Exchange student (Twin College Envoys Program: TWINCLE) at Chiba University.

Scholarship and Awards

- 1) 令和 4 年度 弘前大学学生表彰,令和 5 年 3 月 7 日.
- 2) 学生奨励賞, 令和 3 年度化学工学会秋田大会, 令和 3 年 7 月 1 日.
- 3) Japanese Government (Monbukagakusho : MEXT) Scholarship, Doctoral course, Hirosaki University, Japan (2019-2023).
